Introduction to Cyclone V Hard Processor System

1

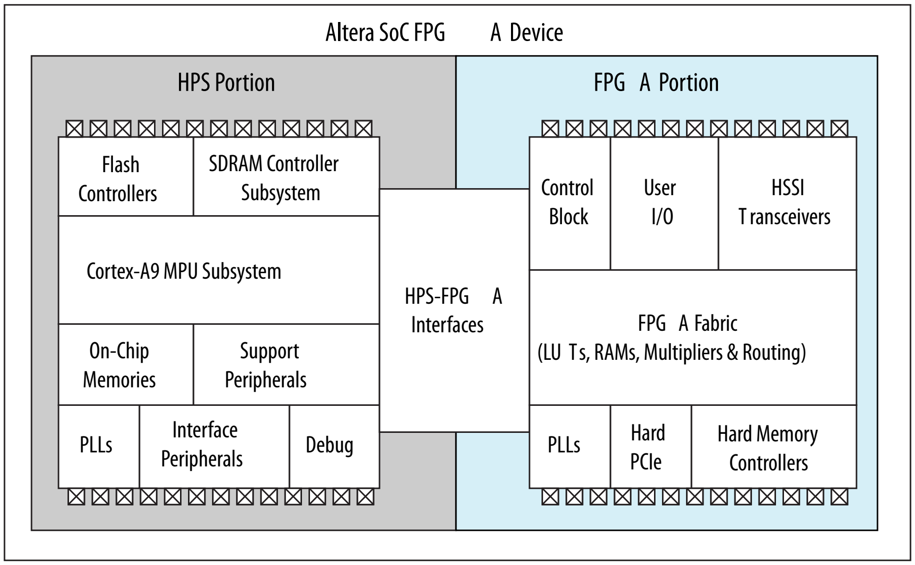
2014.07.31

cv_54001 Subscribe Send Feedback

The Cyclone V device is a single-die system on a chip (SoC) that consists of two distinct parts—a hard processor system (HPS) portion and an FPGA portion.

The following figure shows a high-level block diagram of the Altera SoC device.

Figure 1-1: Altera SoC FPGA Device Block Diagram



The HPS contains a microprocessor unit (MPU) subsystem with single or dual ARM® Cortex®-A9 MPCore processors, flash memory controllers, SDRAM L3 Interconnect, on-chip memories, support peripherals, interface peripherals, debug capabilities, and phase-locked loop (PLLs). The dual-processor HPS supports symmetric (SMP) and asymmetric (AMP) multiprocessing.

The FPGA portion of the device contains the FPGA fabric, a control block (CB), phase-locked loops (PLLs), and depending on the device variant, high-speed serial interface (HSSI) transceivers, hard PCI Express® (PCIe®) controllers, and hard memory controllers.

The HPS and FPGA portions of the device are distinctly different. The HPS can boot from multiple sources, including the FPGA fabric and external flash. In contrast, the FPGA must be configured through either the HPS or an externally supported device.

The HPS and FPGA portions of the device each have their own pins. Pins are not freely shared between the HPS and the FPGA fabric. The HPS I/O pins are configured by software executing in the HPS. Software executing on the HPS accesses control registers in the system manager to assign HPS I/O pins to the available HPS modules. The FPGA I/O pins are configured by an FPGA configuration image through the HPS or any external source supported by the device.

The MPU subsystem can boot from flash devices connected to the HPS pins. Or, when the FPGA portion is configured by an external source, the MPU subsystem can boot from memory available to the FPGA portion of the device.

The HPS and FPGA portions of the device have separate external power supplies and independently power on. You can power on the HPS without powering on the FPGA portion of the device. However, to power on the FPGA portion, the HPS must already be on or powered on at the same time as the FPGA portion. You can also turn off the FPGA portion of the device while leaving the HPS power on.

Related Information

- **Cyclone V Device Overview**
  For information about the FPGA portion of the device, refer to *Cyclone V Device Handbook*.
- **Booting and Configuration Introduction** on page 30-1

Features of the HPS

The following list contains the main modules of the HPS:

- MPU subsystem featuring dual ARM Cortex-A9 MPCore processors
- General-purpose Direct Memory Access (DMA) controller
- Two Ethernet media access controllers (EMACs)
- Two USB 2.0 On-The-Go (OTG) controllers
- NAND flash controller
- Quad SPI flash controller
- Secure Digital (SD) / MultiMediaCard (MMC) controller
- Two serial peripheral interface (SPI) master controllers
- Two SPI slave controllers
- Four inter-integrated circuit (I^2C) controllers
- 64 KB on-chip RAM
- 64 KB on-chip boot ROM
- Two UARTs
- Four timers
- Two watchdog timers
- Three general-purpose I/O (GPIO) interfaces
- Two controller area network (CAN) controllers
- ARM CoreSight™ debug components
  - Debug Access Port (DAP)
  - Trace Port Interface Unit (TPIU)
  - System Trace Macrocell (STM)
  - Program Trace Macrocell (PTM)
  - Embedded Trace Router (ETR)
  - Embedded Cross Trigger (ECT)
- System Manager

- Clock Manager
- Reset Manager
- Scan manager
- FPGA manager

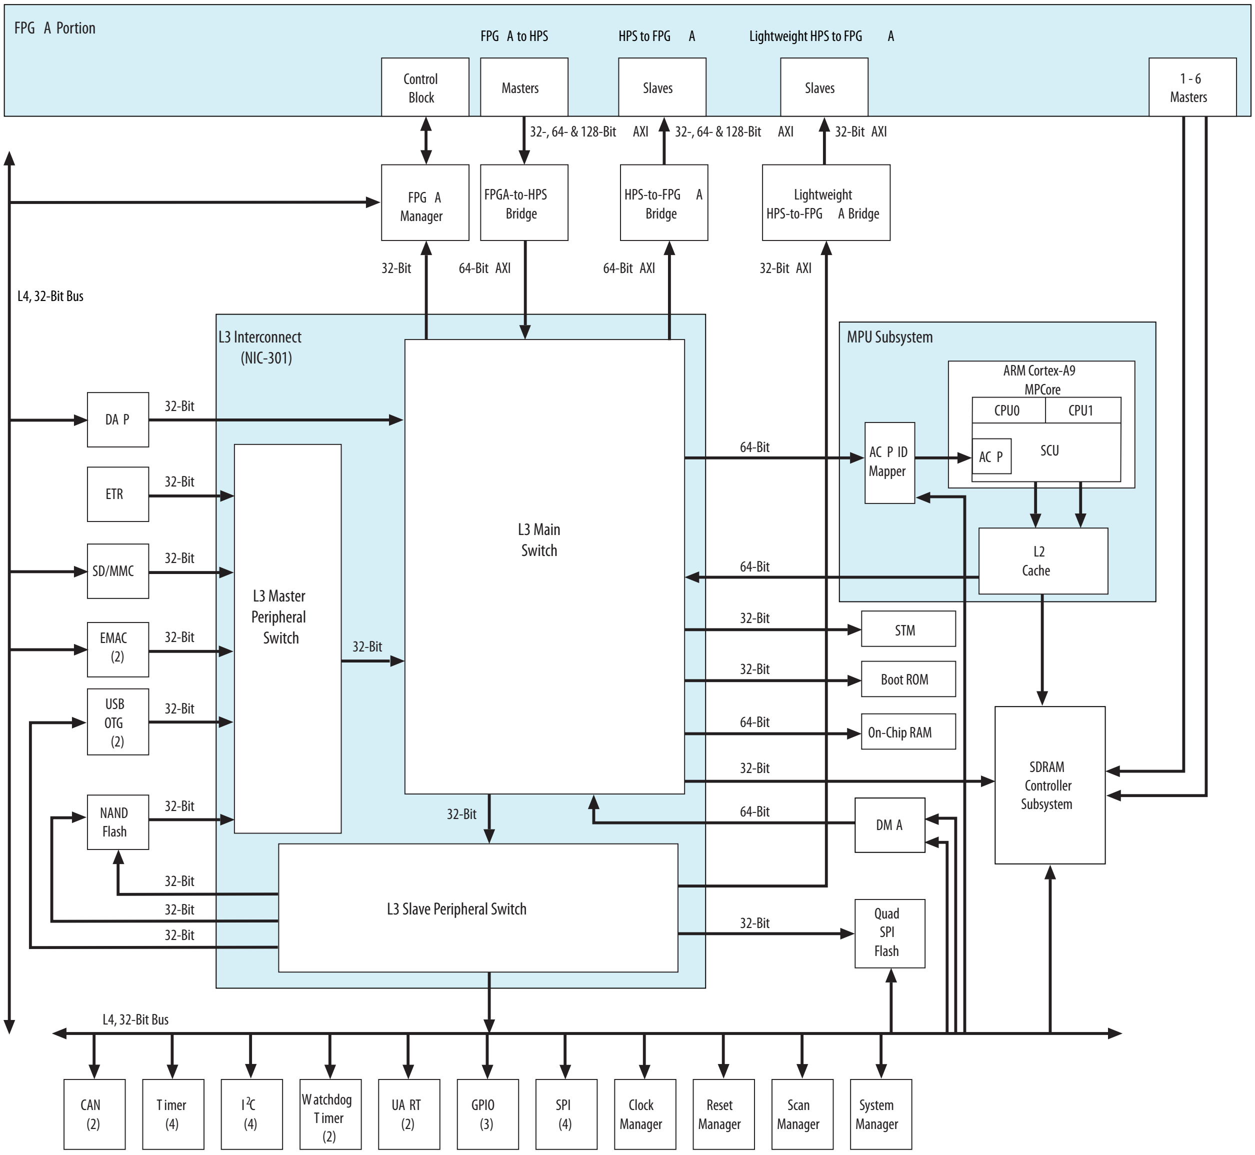
HPS Block Diagram and System Integration

The following figure shows a block diagram of the HPS, excluding the debug system module.

Note: The HPS incorporates third-party intellectual property (IP) from several vendors.

HPS Block Diagram

Figure 1-2: HPS Block Diagram



MPU Subsystem

The MPU subsystem provides the following functionality:

- ARM Cortex-A9 MPCore
  - One or two ARM Cortex-A9 processors in a cluster
  - NEON™ Single Instruction, Multiple Data (SIMD) coprocessor and Vector Floating-Point v3 (VFPv3) per processor
  - Snoop Control Unit (SCU) to ensure coherency within the cluster
  - Accelerator coherency port (ACP) that accepts coherency memory access requests
  - Interrupt controller
  - One general-purpose timer and one watchdog timer per processor
  - Debug and trace features
  - 32 KB instruction and 32 KB data level 1 (L1) caches per processor
  - Memory management unit (MMU) per processor
- ARM L2-310 level 2 (L2) cache
  - Shared 512 KB L2 cache
- ACP ID mapper
- Maps the 12-bit ID from the level 3 (L3) interconnect to the 3-bit ID supported by the ACP

As shown in the "HPS Block Diagram", the L2 cache has one 64-bit master port that is connected to the L3 interconnect, one 64-bit master port connected to the SDRAM L3 Interconnect, and three ports that connect the FPGA to the SDRAM L3 Interconnect. A programmable address filter in the L2 cache controls which portions of the 32-bit physical address space use each master.

Related Information

- **HPS Block Diagram** on page 1-3
- **Cortex-A9 Microprocessor Unit Subsystem** on page 9-1

Interconnect

The interconnect consists of the L3 interconnect and level 4 (L4) buses. The L3 interconnect is an ARM NIC-301 module composed of the following switches:

- L3 main switch
  - Connects the master, slaves, and other subswitches
  - Provides 64-bit switching capabilities
- L3 master peripheral switch
  - Connects master ports of peripherals with integrated DMA controllers to the L3 main switch
- L3 slave peripheral switch
  - Connects slave ports of peripherals to the L3 main switch

The L4 buses are each connected to a master in the L3 slave peripheral switch.

- Each L4 bus is 32 bits wide and is connected to multiple slaves.
- Each L4 bus operates on a separate clock source.

Related Information

System Interconnect on page 7-1

Memory Controllers

SDRAM Controller Subsystem

The SDRAM controller subsystem is mastered by HPS masters and FPGA fabric masters.

The SDRAM controller subsystem implements the following high-level features:

- Support for double data rate 2 (DDR2), DDR3, and low-power double data rate 2 (LPDDR2) devices
- Software-configurable priority scheduling on individual SDRAM bursts
- Error correction code (ECC) support, including calculation, single-bit error correction and write-back, and error counters
- Fully-programmable timing parameter support for all JEDEC-specified timing parameters
- All ports support memory protection and mutual accesses
- Support for ARM Advanced Microcontroller Bus Architecture (AMBA®) Advanced eXtensible Interface (AXI™) quality of service (QoS) for the fabric interfaces

The SDRAM controller subsystem is composed of the SDRAM controller and the DDR PHY.

Related Information

Functional Description—HPS Memory Controller on page 11-1

SDRAM Controller

The SDRAM controller contains a multiport front end (MPFE) that accepts requests from HPS masters and from soft logic in the FPGA fabric via the FPGA-to-HPS SDRAM interface.

The SDRAM controller offers the following features:

- Up to 4 GB address range
- 8-, 16-, and 32-bit data widths
- Optional ECC support
- Low-voltage 1.35V DDR3L and 1.2V DDR3U support
- Full memory device power management support
- Two chip selects

The SDRAM controller provides the following features to maximize memory performance:

- Command reordering (look-ahead bank management)
- Data reordering (out of order transactions)
- Deficit round-robin arbitration with aging for bandwidth management
- High-priority bypass for latency sensitive traffic

Related Information

Functional Description—HPS Memory Controller on page 11-1

DDR PHY

The DDR PHY interfaces the single port memory controller to the HPS memory I/O.

Related Information

Functional Description—HPS Memory Controller on page 11-1

NAND Flash Controller

The NAND flash controller is based on the Cadence®Design IP® NAND Flash Memory Controller and offers the following functionality and features:

- Supports one x8 NAND flash device
- Supports Open NAND Flash Interface (ONFI) 1.0
- Supports NAND flash memories from Hynix, Samsung, Toshiba, Micron, and ST Micro
- Supports programmable 512 byte (4-, 8-, or 16-bit correction) or 1024 byte (24-bit correction) error correction code (ECC) sector size
- Supports pipeline read-ahead and write commands for enhanced read/write throughput
- Supports devices with 32, 64, 128, 256, 384, or 512 pages per block
- Supports multiplane devices
- Supports page sizes of 512 bytes, 2 kilobytes (KB), 4 KB, or 8 KB
- Supports single-level cell (SLC) and multi-level cell (MLC) devices with programmable correction capabilities
- Provides internal direct memory access (DMA)
- Provides programmable access timing

Related Information

NAND Flash Controller on page 13-1

Quad SPI Flash Controller

The Quad SPI flash controller is based on Cadence Quad SPI Flash Controller and offers the following features:

- Supports SPIx1, SPIx2, or SPIx4 (Quad SPI) serial NOR flash devices
- Supports direct access and indirect access modes.
- Supports single, dual, and quad I/O instructions
- Programmable data frame size of 8, 16, or 32 bits
- Support up to four chip selects

Related Information

Quad SPI Flash Controller on page 15-1

SD/MMC Controller

The SD/MMC controller is based on Synopsys® DesignWare® Mobile Storage Host controller and offers the following features:

- Integrated descriptor-based DMA
- Supports CE-ATA digital protocol commands
- Supports single card
- Single data rate (SDR) mode only
- Programmable card width: 1-, 4-, and 8-bit
- Programmable card types: SD, SDIO, or MMC version 4.3 and 4.4 devices
- Up to 64 KB programmable block size

Note: For an inclusive list of the programmable card types versions supported, refer to the *SD/MMC Controller* chapter.

Related Information

SD/MMC Controller on page 14-1

Support Peripherals

Clock Manager

The clock manager offers the following features:

- Manages clocks for HPS
- Supports dynamic clock tuning

Related Information

Clock Manager on page 2-1

Reset Manager

The reset manager manages resets for HPS.

Related Information

Reset Manager on page 3-1

System Manager

The system manager offers the following features:

- ECC monitoring and control
- Pin multiplexing
- Low-level control of peripheral features not accessible through the control and status registers (CSRs)
- Freeze controller that places I/O elements into a safe state for configuration

Related Information

System Manager on page 5-1

Scan Manager

The scan manager drives serial scan-chains to FPGA JTAG and HPS I/O bank configuration.

Related Information

Scan Manager on page 6-1

Timers

The four timers are based on the Synopsys DesignWare APB Timer peripheral and offer the following features:

- 32-bit timer resolution
- Free-running timer mode
- Programmable time-out period up to approximately 86 seconds (assuming a 50 MHz input clock frequency)
- Interrupt generation

Related Information

Timer on page 23-1

Watchdog Timers

The two watchdog timers are based on the Synopsys DesignWare APB Watchdog Timer peripheral and offer the following features:

- 32-bit timer resolution
- Interrupt request
- Reset request
- Programmable time-out period up to approximately 86 seconds (assuming a 50 MHz input clock frequency)

Related Information

Watchdog Timer on page 24-1

DMA Controller

The DMA controller provides high-bandwidth data transfers for modules without integrated DMA controllers. The DMA controller is based on the ARM Corelink™ DMA Controller (DMA-330) and offers the following features:

- Micro-coded to support flexible transfer types
- Supports up to eight channels
- Supports flow control with 31 peripheral handshake interfaces

Related Information

DMA Controller on page 16-1

FPGA Manager

The FPGA manager offers the following features:

- Manages configuration of the FPGA portion of the device
- 32-bit fast passive parallel configuration interface to the FPGA CSS block
- Partial reconfiguration
- Compressed FPGA configuration images
- Advanced Encryption Standard (AES) encrypted FPGA configuration images
- Monitors configuration-related signals in FPGA
- Provides 32 general-purpose inputs and 32 general-purpose outputs to the FPGA fabric

Related Information

FPGA Manager on page 4-1

Interface Peripherals

EMACs

The two EMACs are based on the Synopsys DesignWare 3504-0 Universal 10/100/1000 Ethernet MAC and offer the following features:

- Supports 10, 100, and 1000 Mbps standard
- Supports RGMII external PHY interface
- Provides full GMII interface when using FPGA interface
- Integrated DMA controller

Related Information

Ethernet Media Access Controller on page 17-1

USB Controllers

The two USB 2.0 On-The-Go (OTG) controllers are based on the Synopsys DesignWare Cores USB 2.0 Hi-Speed On-The-Go controller and offer the following features:

- Complies with both Revision 1.3 and Revision 2.0 of the "On the Go and Embedded Host Supplement to the USB Revision 2.0 Specification
- Supports software-configurable modes of operation between OTG 1.3 and OTG 2.0
- Supports all USB 2.0 speeds:
  - High speed (HS, 480-Mbps)
  - Full speed (FS, 12-Mbps)
  - Low speed (LS, 1.5-Mbps)

  Note: In host mode, all speeds are supported. However, in device mode, only high speed and full speed are supported.

Ont the integration side, the USB OTG controller supports the following features:

- Different clocks for system and PHY interfaces
- Dedicated TX FIFO buffer for each device IN endpoint in direct memory access (DMA) mode
- Packet-based, dynamic FIFO memory allocation for endpoints for small FIFO buffers and flexible, efficient use of RAM that can be dynamically sized by software
- Ability to change an endpoint's FIFO memory size during transfers
- Clock gating support during USB suspend and session-off modes
  - PHY clock gating support
  - System clock gating support
- Data FIFO RAM clock gating support
- Local buffering with error correction code (ECC) support

  Note: The USB OTG controller does not support the following protocols:

  - Enhanced Host Controller Interface (EHCI)
  - Open Host Controller Interface (OHCI)
  - Universal Host Controller Interface (UHCI)
- Supports USB 2.0 ULPI PHYs (SDR mode only)
- Supports up to 16 bidirectional endpoints, including control endpoint 0

  Note: Only seven periodic device IN endpoints are supported.
- Supports up to 16 host channels

  Note: In host mode, when the number of device endpoints is greater than the number of host channels, software can reprogram the channels to support up to 127 devices, each having 32 endpoints (IN + OUT), for a maximum of 4,064 endpoints
- Supports generic root hub
- Supports automatic ping capability

Related Information

USB 2.0 OTG Controller on page 18-1

I^{2}C Controllers

The four I^{2}C controllers are based on Synopsys DesignWare APB I^{2}C controller and offer the following features:

- Two controllers support I^{2}C management interfaces for the EMAC controllers which are for Ethernet control
- Support both 100 KBps and 400 KBps modes
- Support both 7-bit and 10-bit addressing modes
- Support master and slave operating mode
- Direct access for host processor
- DMA controller may be used for large transfers

Related Information

I^{2}C Controller on page 20-1

UARTs

The two UART modules are based on Synopsys DesignWare APB Universal Asynchronous Receiver/ Transmitter peripheral and offer the following features:

- 16550 compatible UART
- Supports the auto flow control as specified in 16750 specification
- Supports IrDA 1.0 SIR mode
- Programmable baud rate up to 115.2 Kbps
- Direct access for host processor
- DMA controller may be used for large transfers

Related Information

UART Controller on page 21-1

CAN Controllers

The two CAN controllers are based on the Bosch® D_CAN controller and offer the following features:

- Compliant with CAN protocol specification 2.0 part A & B
- Programmable communication rate up to 1 Mbps
- Holds up to 128 messages
- Supports 11-bit standard and 29-bit extended identifiers
- Programmable interrupt scheme
- Direct access for host processor
- DMA controller may be used for large transfers
- Available on certain device variants only

Related Information

CAN Controller Introduction on page 25-1

SPI Master Controllers

The two SPI master controllers are based on Synopsys DesignWare Synchronous Serial Interface (SSI) controller and offer the following features:

- Programmable data frame size from 4 to 16 bits
- Supports full- and half-duplex
- Supports up to four chip selects
- Direct access for host processor
- DMA controller may be used for large transfers

Related Information

SPI Controller on page 19-1

SPI Slave Controllers

The two SPI slave controllers are based on Synopsys DesignWare Synchronous Serial Interface (SSI) controller and offer the following features:

- Programmable data frame size from 4 to 16 bits
- Supports full- and half-duplex
- Direct access for host processor
- DMA controller may be used for large transfers

Related Information

SPI Controller on page 19-1

GPIO Interfaces

The HPS provides three GPIO interfaces that are based on Synopsys DesignWare APB General Purpose Programming I/O peripheral and offer the following features:

- Supports digital de-bounce
- Configurable interrupt mode
- Supports up to 71 I/O pins and 14 input-only pins, based on device variant
- Supports up to 67 I/O pins and 14 input-only pins

Related Information

General-Purpose I/O Interface on page 22-1

On-Chip Memory

On-Chip RAM

The on-chip RAM offers the following features:

- 64 KB size
- 64-bit slave interface
- High performance for all burst lengths

Related Information

On-Chip Memory on page 12-1

Boot ROM

The boot ROM offers the following features:

- 64 KB size
- Contains the code required to support HPS boot from cold or warm reset
- Used exclusively for booting the HPS

Related Information

On-Chip Memory on page 12-1

Endian Support

The HPS is natively a little-endian system. All HPS slaves are little-endian.

The processors masters are software configurable to interpret data as little-endian or big-endian, byte-invariant (BE8). All other masters, including the USB interface, are little-endian.

The FPGA-to-HPS, HPS-to-FPGA, FPGA-to-SDRAM, and lightweight HPS-to-FPGA interfaces are little-endian.

If a processor is set to BE8 mode, software must convert endianness for accesses to peripherals and DMA linked lists in memory.

The ARM Cortex-A9 MPU supports a single instruction to change the endianness of the processor and provides the REV and REV16 instructions to swap the endianness of bytes or half-words respectively. The MMU page tables are software configurable to be organized as little-endian or BE8.

The ARM DMA controller is software configurable to perform byte lane swapping during a transfer.

HPS-FPGA Interfaces

The HPS-FPGA interfaces provide a variety of communication channels between the HPS and the FPGA fabric. The HPS is highly integrated with the FPGA fabric, resulting in thousands of connecting signals. The HPS-FPGA interfaces include:

- FPGA-to-HPS bridge—a high-performance bus with a configurable data width of 32, 64, and 128 bits, allowing the FPGA fabric to master transactions to the slaves in the HPS. This interface allows the FPGA fabric to have full visibility into the HPS address space. This interface also provides access to the coherent memory interface.
- HPS-to-FPGA bridge—a high-performance interface with a configurable data width of 32, 64, and 128 bits, allowing the HPS to master transactions to slaves in the FPGA fabric.
- Lightweight HPS-to-FPGA bridge—an interface with a 32-bit fixed data width, allowing the HPS to master transactions to slaves in the FPGA fabric.
- FPGA clocks and resets—provide flexible clocks to and from the HPS.
- HPS-to-FPGA JTAG—allows the HPS to master the FPGA JTAG chain.
- TPIU trace—sends trace data created in the HPS to the FPGA fabric.
- FPGA System Trace Macrocell (STM) events—an interface that allows the FPGA fabric to send hardware events stored in the HPS trace using STM.
- FPGA cross-trigger—an interface that allows triggers to and from the CoreSight trigger system.
- DMA peripheral interface—multiple peripheral-request channels.
- FPGA manager interface—signals that communicate with FPGA fabric for boot and configuration.

- Interrupts—allow soft IP to supply interrupts directly to the MPU interrupt controller.
- MPU standby and events—signals that notify the FPGA fabric that the MPU is in standby mode and signals that wake up Cortex-A9 processors from a wait for event (WFE) state.
- HPS debug interface - an interface that allows HPS debug control domain (debug APB) to extend into FPGA

Related Information

HPS-FPGA Bridges on page 8-1

HPS Address Map

The address map specifies the addresses of slaves, such as memory and peripherals, as viewed by the MPU and other masters. The HPS has multiple address spaces, defined in the following section.

HPS Address Spaces

The following table shows the HPS address spaces and their sizes.

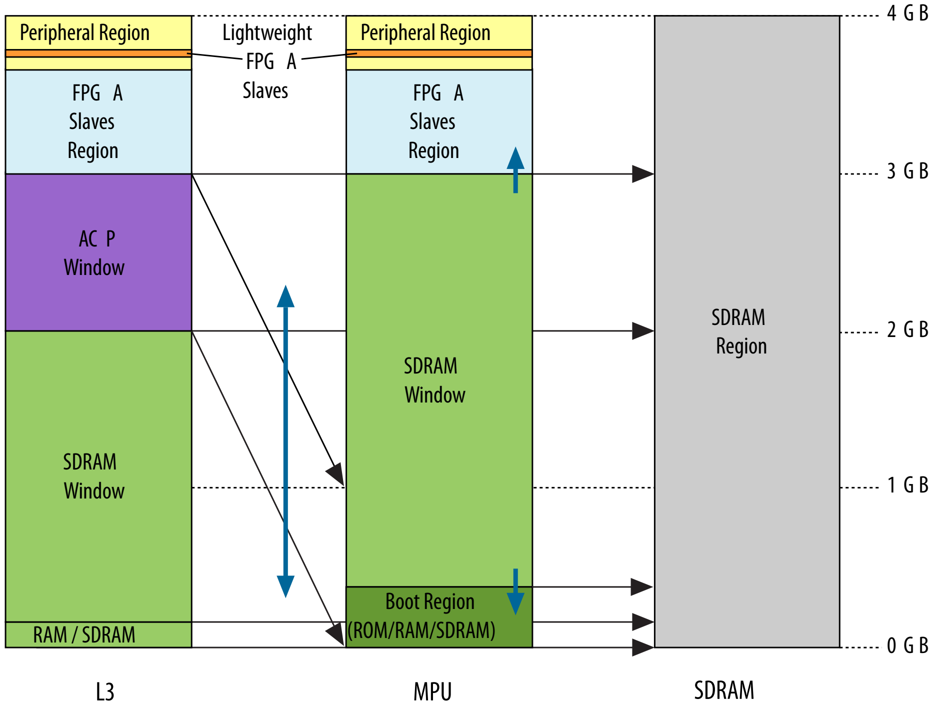
Table 1-1: HPS Address Spaces

Name	Description	Size
MPU	MPU subsystem	4 GB
L3	L3 interconnect	4 GB
SDRAM	SDRAM controller subsystem	4 GB

Address spaces are divided into one or more nonoverlapping regions. For example, the MPU address space has the peripheral, FPGA slaves, SDRAM window, and boot regions.

The following figure shows the relationships between the HPS address spaces. The figure is not to scale.

Figure 1-3: HPS Address Space Relationships



The window regions provide access to other address spaces. The thin black arrows indicate which address space is accessed by a window region (arrows point to accessed address space). For example, accesses to the ACP window in the L3 address space map to a 1 GB region of the MPU address space.

The SDRAM window in the MPU address space can grow and shrink at the top and bottom (short, blue vertical arrows) at the expense of the FPGA slaves and boot regions. For specific details, refer to “MPU Address Space”.

The ACP window can be mapped to any 1 GB region in the MPU address space (blue vertical bidirectional arrow), on gigabyte-aligned boundaries.

The following table shows the base address and size of each region that is common to the L3 and MPU address spaces.

Table 1-2: Common Address Space Regions

Identifier	Region Name	Base Address	Size
FPGASLAVES	FPGA slaves	0xC0000000	960 MB
PERIPH	Peripheral	0xFC000000	64 MB
LWFPGASLAVES [1]	Lightweight FPGA slaves	0xFF200000	2 MB

[1] This space is part of the "PERIPH" space.

Related Information

MPU Address Space on page 1-15

SDRAM Address Space

The SDRAM address space is up to 4 GB. The entire address space can be accessed through the FPGA-to-HPS SDRAM interface from the FPGA fabric. The total amount of SDRAM addressable from the other address spaces can be configured at runtime.

Related Information

- MPU Address Space on page 1-15
- L3 Address Space on page 1-15
- Interconnect on page 1-4
  For details of how to configure the SDRAM address space.

MPU Address Space

The MPU address space is 4 GB and applies to addresses generated inside the MPU. The MPU address space contains the following regions:

- The SDRAM window region provides access to a large, configurable portion of the 4 GB SDRAM address space.
- The MPU L2 cache controller contains a master connected to the L3 interconnect and a master connected to the SDRAM.
- The address filtering start and end registers in the L2 cache controller define the SDRAM window boundaries.
  - The boundaries are megabyte-aligned.
  - Addresses within the boundaries route to the SDRAM master.
  - Addresses outside the boundaries route to the L3 interconnect master.

Related Information

- HPS Address Spaces on page 1-13
  For more information, refer to the "HPS Address Space Relationships" table.

  For information about the L3 `remap` control register bits, refer to the *Interconnect* chapter.
- Cortex-A9 Microprocessor Unit Subsystem on page 9-1
  For details about L2 address filtering, refer to the *Cortex-A9 Microprocessor Unit Subsystem* chapter.

L3 Address Space

The L3 address space is 4 GB and applies to all L3 masters except the MPU. The L3 address space has more configuration options than the other address spaces.

Related Information

- System Interconnect on page 7-1
  For information about the L3 `remap` control register bits, refer to the *Interconnect* chapter.

Clock Manager 2

2014.06.30

cv_54002 Subscribe Send Feedback

The hard processor system (HPS) clock generation is centralized in the *Clock Manager*. The *Clock Manager* is responsible for providing software-programmable clock control to configure all clocks generated in the HPS. Clocks are organized in clock groups. A clock group is a set of clock signals that originate from the same clock source. A phase-locked loop (PLL) clock group is a clock group where the clock source is a common PLL voltage-controlled oscillator (VCO).

Features of the Clock Manager

The *Clock Manager* offers the following features:

- Generates and manages clocks in the HPS
- Contains the following PLL clock groups:
  - Main—contains clocks for the Cortex-A9 microprocessor unit (MPU) subsystem, level 3 (L3) interconnect, level 4 (L4) peripheral bus, and debug
  - Peripheral—contains clocks for PLL-driven peripherals
  - SDRAM—contains clocks for the SDRAM subsystem
- Allows scaling of the MPU subsystem clocks without disabling peripheral and SDRAM clock groups
- Generates clock gate controls for enabling and disabling most clocks
- Initializes and sequences clocks for the following events:
  - Cold reset
  - Safe mode request from reset manager on warm reset

- Allows software to program clock characteristics, such as the following items discussed later in this chapter:
    - Input clock source for SDRAM and peripheral PLLs
    - Multiplier range, divider range, and six post-scale counters for each PLL
    - Output phases for SDRAM PLL outputs
    - VCO enable for each PLL
    - Bypass modes for each PLL
    - Gate off individual clocks in all PLL clock groups
    - Clear loss of lock status for each PLL
    - Safe mode for Hardware-Managed clocks
    - General-purpose I/O (GPIO) debounce clock divide
- Allows software to observe the status of all writable registers
- Supports interrupting the MPU subsystem on PLL-lock and loss-of-lock
- Supports clock gating at the signal level

The *Clock Manager* is **not** responsible for the following functional behaviors:

- Selection or management of the clocks for the FPGA-to-HPS, HPS-to-FPGA, and FPGA-to-HPS SDRAM interfaces. The FPGA logic designer is responsible for selecting and managing these clocks.
- Software must not program the *Clock Manager* with illegal values. If it does, the behavior of the clock manager is undefined and could stop the operation of the HPS. The only guaranteed means for recovery from an illegal clock setting is a cold reset.

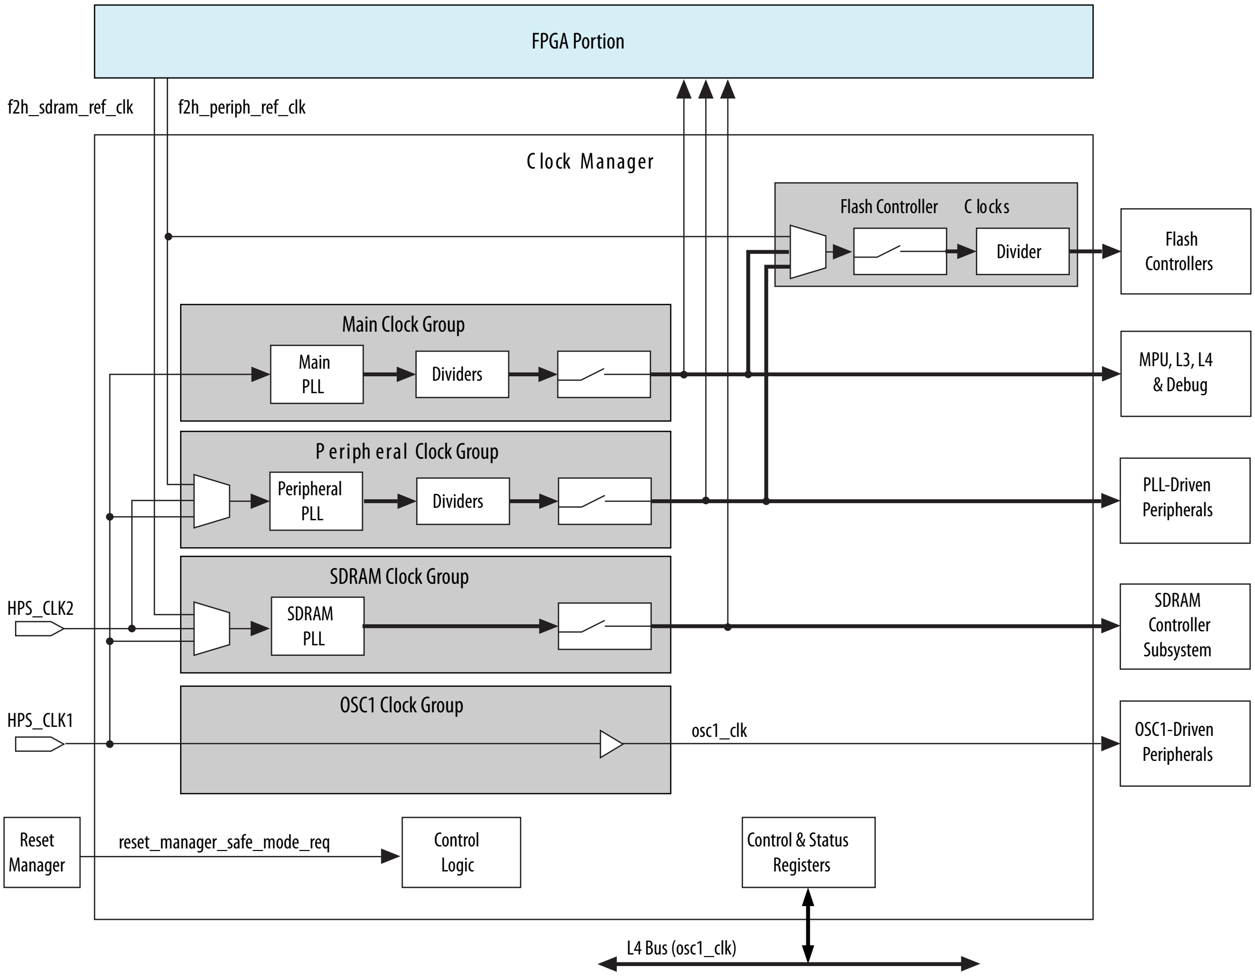
Related Information

Hardware-Managed and Software-Managed Clocks on page 2-5
When re-programming clock settings, there are no automatic glitch-free clock transitions. Software must follow a specific sequence to ensure glitch-free clock transitions. Refer to *Hardware-Managed and Software-Managed Clocks* section of this chapter.

Clock Manager Block Diagram and System Integration

Figure 2-1: Clock Manager Block Diagram

The following figure shows the major components of the clock manager and its integration in the HPS.



Functional Description of the Clock Manager

Clock Manager Building Blocks

PLLs

The *Clock Manager* contains three PLLs: main, peripherals, and SDRAM. These PLLs generate the majority of clocks in the HPS. There is no phase control between the clocks generated by the three PLLs.

Each PLL has the following features:

- Phase detector and output lock signal generation
- Registers to set VCO frequency
  - Multiplier range is 1 to 4096
  - Divider range is 1 to 64
- Six post-scale counters (C0-C5) with a range of 1 to 512
- PLL can be enabled to bypass all outputs to the `osc1_clk` clock for glitch-free transitions

The SDRAM PLL has the following additional feature:

- Phase shift of 1/8 per step
  - Phase shift range is 0 to 7

FREF, FVCO, and FOUT Equations

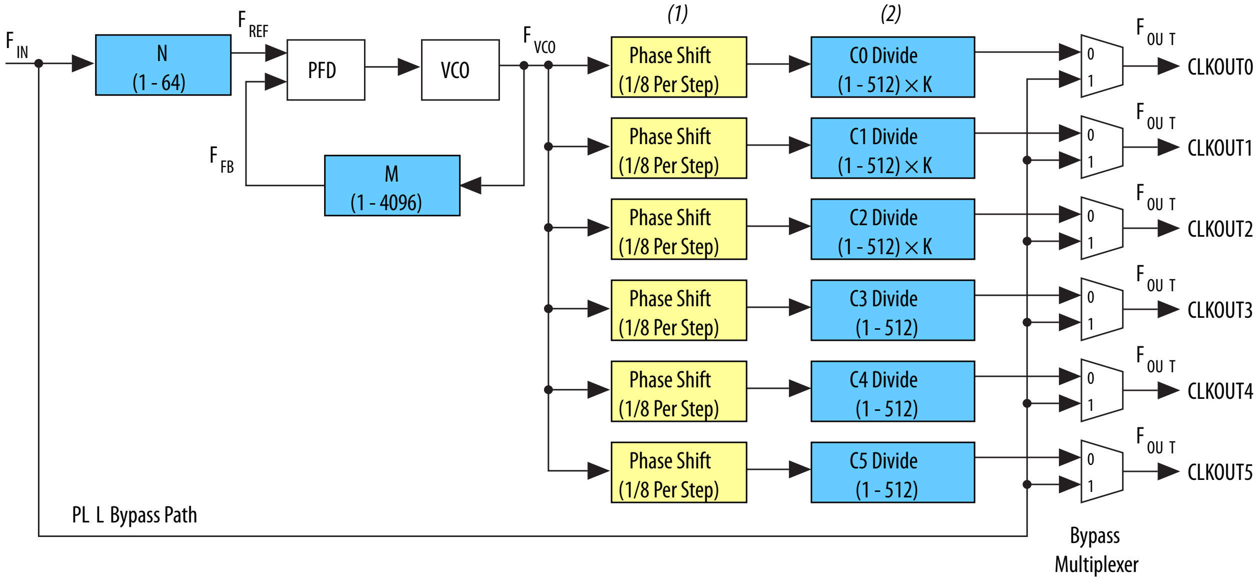
$$
\begin{aligned}
FREF &= F_{IN} / N \\
FVCO &= F_{REF} \times M = F_{IN} \times M/N \\
FOUT &= F_{VCO} / (C_i \times K) = F_{REF} \times M/ (C_i \times K) = (F_{IN} \times M)/ (N \times C_i \times K)
\end{aligned}
$$

where:

- FVCO = VCO frequency.
- FIN = input frequency.
- FREF = reference frequency.
- M = numerator, part of the clock feedback path.
- N = denominator, part of the input clock reference path.
- Ci = post-scale counter, where *i* is 0-5 for each of the six counters.
- K is an internal post-scale counter in the main PLL, where the reset values are K = 2 for C0, and K = 4 for C1 and C2.

Figure 2-2: PLL Block Diagram

Values listed for M, N, and C are actually one greater than the values stored in the CSRs.



Related Information

Cyclone V Device Datasheet

Minimum and maximum VCO frequencies for the main, peripheral, and SDRAM PLLs vary by device speed grade. For specific details, refer the Cyclone V Device Datasheet.

Dividers

Dividers subdivide the C0-C15 clocks produced by the PLL to lower frequencies. The main PLL C0-C2 clocks have an additional internal post-scale counter.

Clock Gating

Clock gating enables and disables clock signals.

Control and Status Registers

The *Clock Manager* contains registers used to configure and observe the clock manager.

Hardware-Managed and Software-Managed Clocks

When changing values on clocks, the terms *Hardware-Managed* and *Software-Managed* define who is responsible for successful transitions. Software-Managed clocks require that software manually gate off any clock affected by the change, wait for any PLL lock if required, then gate the clocks back on. Hardware-Managed clocks use hardware to ensure that a glitch-free transition to a new clock value occurs. There are three Hardware-Managed sets of clocks in the HPS, namely, clocks generated from the main PLL outputs C0, C1, and C2. All other clocks in the HPS are Software-Managed clocks.

Clock Groups

The clock manager contains one clock group for each PLL and one clock group for the `HPS_CLK1` pin.

OSC1 Clock Group

The clock in the OSC1 clock group is derived directly from the `HPS_CLK1` pin. This clock is never gated or divided.

It is used as a PLL input and also by HPS logic that does not operate on a clock output from a PLL.

Table 2-1: OSC1 Clock Group Clock

Name	Frequency	Clock Source	Destination
`osc1_clk`	10 to 50 MHz	`HPS_CLK1` pin	OSC1-driven peripherals listed in Table 2–9 on page 2–14

Main Clock Group

The main clock group consists of a PLL, dividers, and clock gating. The clocks in the main clock group are derived from the main PLL. The main PLL is always sourced from the `HPS_CLK1` pin of the device.

Table 2-2: Main PLL Output Assignments

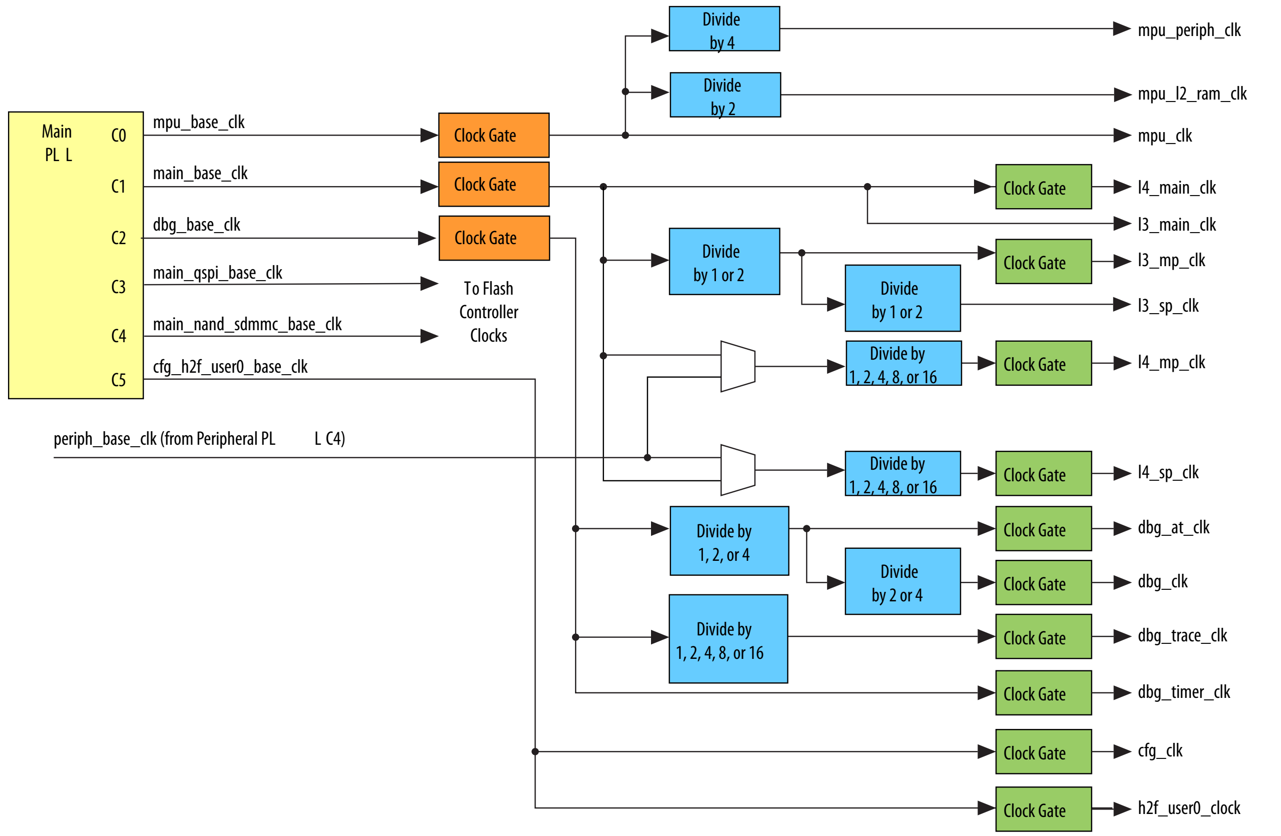
PLL	Output Counter	Clock Name	Frequency	Phase Shift Control
Main	C0	mpu_base_clk	osc1_clk to varies [2]	No
	C1	main_base_clk	osc1_clk to varies [2]	No
	C2	dbg_base_clk	osc1_clk/4 to mpu_base_clk/2	No
	C3	main_qspi_base_clk	Up to 432 MHz	No
	C4	main_nand_sdmmc_base_clk	Up to 250 MHz for the NAND flash controller and up to 200 MHz for the SD/MMC controller	No
	C5	cfg_h2f_user0_base_clk	osc1_clk to 125 MHz for driving configuration and 100 MHz for the user clock	No

The counter outputs from the main PLL can have their frequency further divided by programmable dividers external to the PLL. Transitions to a different divide value occur on the fastest output clock, one clock cycle prior to the slowest clock's rising edge. For example, cycle 15 of the divide-by-16 divider for the main C2 output and cycle 3 of the divide-by-4 divider for the main C0 output.

The following figure shows how each counter output from the main PLL can have its frequency further divided by programmable post-PLL dividers. Green-colored clock gating logic is directly controlled by software writing to a register. Orange-colored clock gating logic is controlled by hardware. Orange-colored clock gating logic allows hardware to seamlessly transition a synchronous set of clocks, for example, all the MPU subsystem clocks.

[2] The maximum frequency depends on the speed grade of the device.

Figure 2-3: Main Clock Group Divide and Gating



The clocks derived from main PLL C0-C2 outputs are hardware-managed, meaning hardware ensures that a clean transition occurs, and can have the following control values changed dynamically by software write accesses to the control registers:

- PLL bypass
- PLL numerator, denominator, and counters
- External dividers

For these registers, hardware detects that the write has occurred and performs the correct sequence to ensure that a glitch-free transition to the new clock value occurs. These clocks can pause during the transition.

Table 2-3: Main Clock Group Clocks

System Clock Name	Freq uency	Constraints and Notes
`mpu_clk`	Main PLL C0	Clock for MPU subsystem, including CPU0 and CPU1
`mpu_l2_ram_clk`	`mpu_clk/2`	Clock for MPU level 2 (L2) RAM

System Clock Name	Freq uency	Constraints and Notes
mpu_periph_clk	mpu_clk/4	Clock for MPU snoop control unit (SCU) peripherals , such as the general interrupt controller (GIC)
l3_main_clk	Main PLL C1	Clock for L3 main switch
l3_mp_clk	l3_main_clk or l3_main_clk/2	Clock for L3 master peripherals (MP) switch
l3_sp_clk	l3_mp_clk or l3_mp_clk/2	Clock for L3 slave peripherals (SP) switch
l4_main_clk	Main PLL C1	Clock for L4 main bus
l4_mp_clk	osc1_clk/16 to 100 MHz divided from main PLL C1 or peripheral PLL C4	Clock for L4 MP bus
l4_sp_clk	osc1_clk/16 to 100 MHz divided from main PLL C1 or peripheral PLL C4	Clock for L4 SP bus
dbg_at_clk	osc1_clk/4 to main PLL C2/2	Clock for CoreSight™ debug trace bus
dbg_trace_clk	osc1_clk/16 to main PLL C2	Clock for CoreSight™ debug Trace Port Interface Unit (TPIU)
dbg_timer_clk	osc1_clk to main PLL C2	Clock for the trace timestamp generator
dbg_clk	dbg_at_clk/2 or dbg_at_clk/4	Clock for Debug Access Port (DAP) and debug peripheral bus
main_qspi_clk	Main PLL C3	Quad SPI flash internal logic clock
main_nand_sdmmc_clk	Main PLL C4	Input clock to flash controller clocks block

System Clock Name	Freq uency	Constraints and Notes
cfg_clk	osc1_clk to 125_MHz divided from main PLL C5	FPGA manager configuration clock
h2f_user0_clock	osc1_clk to 100_MHz divided from main PLL C5	Auxiliary user clock to the FPGA fabric

Changing Values That Affect Main Clock Group PLL Lock

To change any value that affects VCO lock of the main clock group PLL, including the hardware-managed clocks, software must put the main PLL in bypass mode, which causes all the main PLL output clocks to be driven by the osc1_clk clock. Software must detect PLL lock by reading the lock status register prior to taking the main PLL out of bypass mode.

Once a PLL is locked, changes to any PLL VCO frequency that are 20 percent or less do not cause the PLL to lose lock. Iteratively changing the VCO frequency in increments of 20 percent or less allow a slow ramp of the VCO base frequency without loss of lock.For example, to change a VCO frequency by 40% without losing lock, change the frequency by 20%, then change it again by 16.7%.

Peripheral Clock Group

The peripheral clock group consists of a PLL, dividers, and clock gating. The clocks in the peripheral clock group are derived from the peripheral PLL. The peripheral PLL can be programmed to be sourced from the HPS_CLK1 pin, the HPS_CLK2 pin, or the f2h_periph_ref_clk clock provided by the FPGA fabric.

The counter outputs from the main PLL can have their frequency further divided by external dividers. Transitions to a different divide value occur on the fastest output clock, one clock cycle prior to the slowest clock’s rising edge. For example, cycle 15 of the divide-by-16 divider for the main C2 output and cycle 3 of the divide-by-4 divider for the C1 output.

Table 2-4: Peripheral PLL Output Assignments

PLL	Output Counter	Clock Name	Frequency	Phase Shift Control
Peripheral	C0	emac0_base_clk	Up to 250 MHz	No
	C1	emac1_base_clk	Up to 250 MHz	No
	C2	periph_qspi_base_clk	Up to 432 MHz	No
	C3	periph_nand_sdmmc_base_clk	Up to 250 MHz for the NAND flash controller and up to 200 MHz for the SD/MMC controller	No
	C4	periph_base_base_clk	Up to 240 MHz for the SPI masters and up to 200 MHz for the scan manager	No
	C5	h2f_user1_base_clk	osc1_clk to 100 MHz	No

The following figure shows programmable post-PLL dividers and clock gating for the peripheral clock group. Clock gate blocks in the diagram indicate clocks which may be gated off under software control. Software is expected to gate these clocks off prior to changing any PLL or divider settings that might create incorrect behavior on these clocks.

Figure 2-4: Peripheral Clock Group Divide and Gating

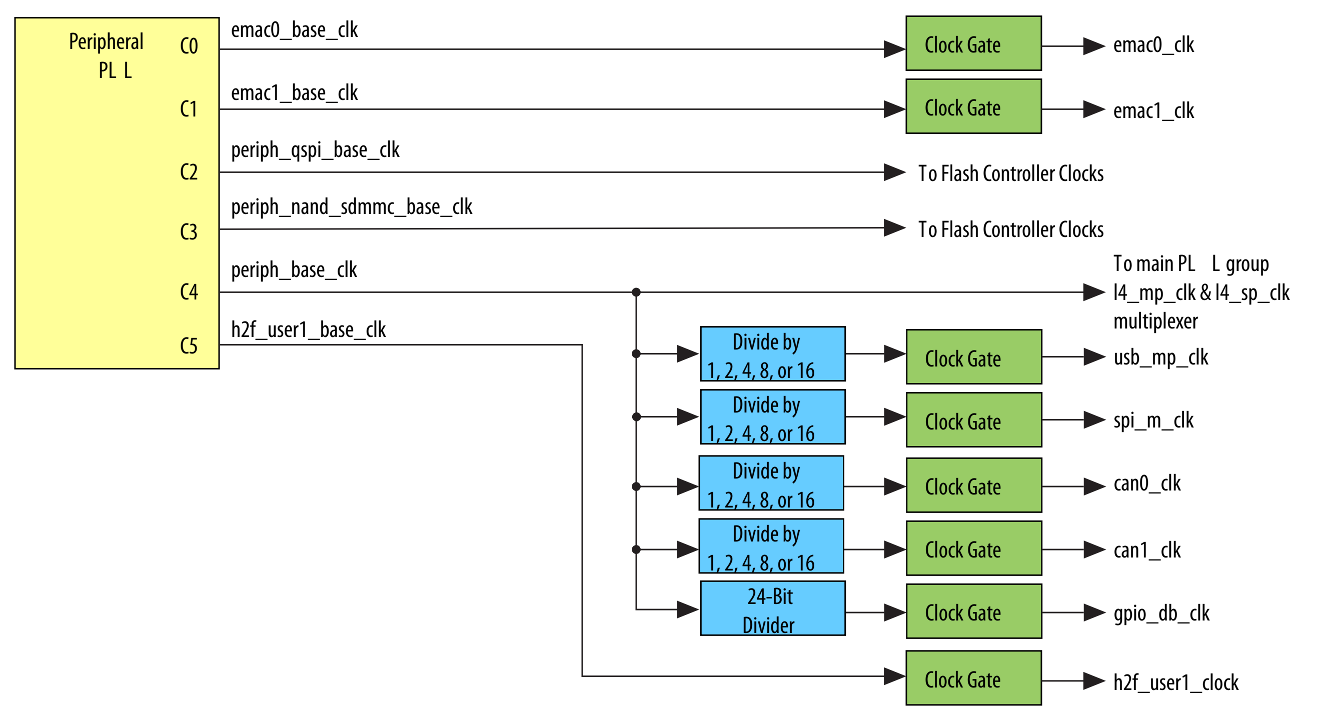


Table 2-5: Peripheral Clock Group Clocks

System Clock Name	Frequency	Divided From	Constraints and Notes
`usb_mp_clk`	Up to 200 MHz	Peripheral PLL C4	Clock for USB
`spi_m_clk`	Up to 240 MHz for the SPI masters and up to 200 MHz for the scan manager	Peripheral PLL C4	Clock for L4 SPI master bus and scan manager
`emac0_clk`	Up to 250 MHz	Peripheral PLL C0	EMAC0 clock. The 250 MHz clock is divided internally by the EMAC into the typical 125/25/2.5 MHz speeds for 1000/100/10 Mbps operation.

System Clock Name	Frequency	Divided From	Constraints and Notes
`emac1_clk`	Up to 250 MHz	Peripheral PLL C1	EMAC1 clock The 250 MHz clock is divided internally by the EMAC into the typical 125/25/2.5 MHz speeds for 1000/100/10 Mbps operation.
`l4_mp_clk`	Up to 100 MHz	Main PLL C1 or peripheral PLL C4	Clock for L4 master peripheral bus
`l4_sp_clk`	Up to 100 MHz	Main PLL C1 or peripheral PLL C4	Clock for L4 slave peripheral bus
`can0_clk`	Up to 100 MHz	Peripheral PLL C4	Controller area network (CAN) controller 0 clock
`can1_clk`	Up to 100 MHz	Peripheral PLL C4	CAN controller 1 clock
`gpio_db_clk`	Up to 1 MHz	Peripheral PLL C4	Used to debounce GPIO0, GPIO1, and GPIO2
`h2f_user1_clock`	Peripheral PLL C5	Peripheral PLL C5	Auxiliary user clock to the FPGA fabric

SDRAM Clock Group

The SDRAM clock group consists of a PLL and clock gating. The clocks in the SDRAM clock group are derived from the SDRAM PLL. The SDRAM PLL can be programmed to be sourced from the `HPS_CLK1` pin, the `HPS_CLK2` pin, or the `f2h_sdram_ref_clk` clock provided by the FPGA fabric.

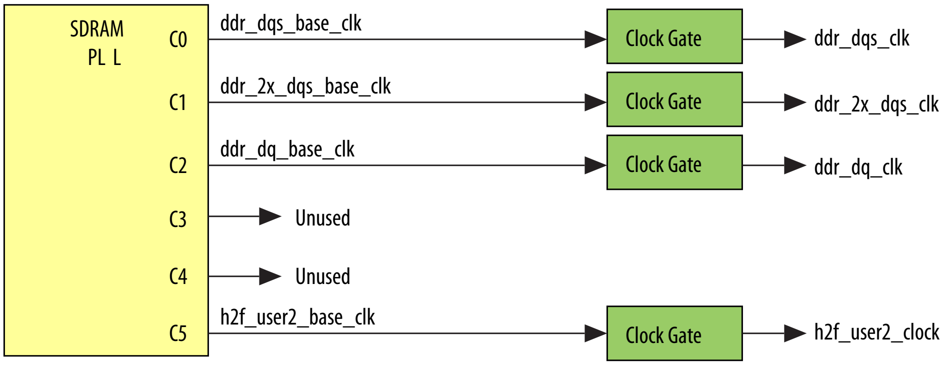
The counter outputs from the SDRAM PLL can be gated off directly under software control. The divider values for each clock are set by registers in the clock manager.

Table 2-6: SDRAM PLL Output Assignments

PLL	Output Counter	Clock Name	Frequency	Phase Shift Control
SDRAM	C0	ddr_dqs_base_clk	Varies [3]	Yes
	C1	ddr_2x_dqs_base_clk	ddr_dqs_base_clk x 2	Yes
	C2	ddr_dq_base_clk	ddr_dqs_base_clk	Yes
	C5	h2f_user2_base_clk	osc1_clk to varies [3]	Yes

The following figure shows clock gating for SDRAM PLL clock group. Clock gate blocks in the diagram indicate clocks which may be gated off under software control. Software is expected to gate these clocks off prior to changing any PLL or divider settings that might create incorrect behavior on these clocks.

Figure 2-5: SDRAM Clock Group Divide and Gating



The SDRAM PLL output clocks can be phase shifted in real time in increments of 1/8 the VCO frequency. Maximum number of phase shift increments is 4096.

Table 2-7: SDRAM Clock Group Clocks

Name	Frequency	Constraints and Notes
ddr_dqs_clk	SDRAM PLL C0	Clock for MPFE, single-port controller, CSR access, and PHY

[3] The maximum frequency depends on the speed grade of the device.

Name	Frequency	Constraints and Notes
ddr_2x_dqs_clk	SDRAM PLL C1	Clock for PHY
ddr_dq_clk	SDRAM PLL C2	Clock for PHY
h2f_user2_clock	SDRAM PLL C5	Auxiliary user clock to the FPGA fabric

Flash Controller Clocks

Flash memory peripherals can be driven by the main PLL, the peripheral PLL, or from clocks provided by the FPGA fabric.

Figure 2-6: Flash Peripheral Clock Divide and Gating

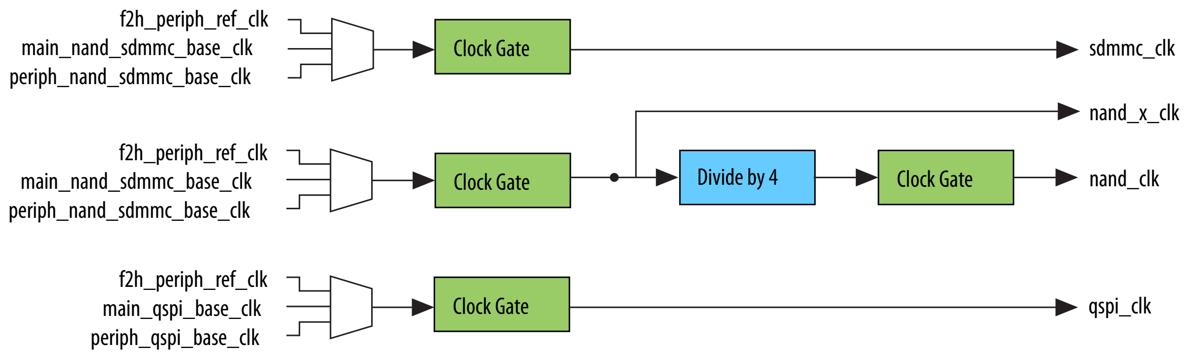


Table 2-8: Flash Controller Clocks

System Clock Name	Freq uency	Divided From	Constraints and Notes
qspi_clk	Up to 432 MHz	Peripheral PLL C2, main PLL C3, or f2h_periph_ref_clk	Clock for quad SPI, typically 108 and 80 MHz
nand_x_clk	Up to 250 MHz	Peripheral PLL C3, main PLL C4, or f2h_periph_ref_clk	NAND flash controller master and slave clock
nand_clk	nand_x_clk/4	Peripheral PLL C3, main PLL C4, or f2h_periph_ref_clk	Main clock for NAND flash controller, sets base frequency for NAND transactions

System Clock Name	Freq uency	Divided From	Constraints and Notes
`sdmmc_clk`	Up to 200 MHz	Peripheral PLL C3, main PLL C4, or `f2h_periph_ref_clk`	• Less than or equal to memory maximum operating frequency • 45% to 55% duty cycle • Typical frequencies are 26 and 52 MHz • SD/MMC has a subclock tree divided down from this clock

Resets

Cold Reset

Cold reset places the hardware-managed clocks into safe mode, the software-managed clocks into their default state, and asynchronously resets all registers in the clock manager.

Related Information

Safe Mode on page 2-15

Warm Reset

Registers in the clock manager control how the clock manager responds to warm reset. Typically, software places the clock manager into a safe state in order to generate a known set of clocks for the ROM code to boot the system. The behavior of the system on warm reset as a whole, including how the FPGA fabric, boot code, and debug systems are configured to behave, must be carefully considered when choosing how the clock manager responds to warm reset.

The reset manager can request that the clock manager go into safe mode as part of the reset manager's warm reset sequence. Before asserting safe mode to the clock manager, the reset manager ensures that the reset signal is asserted on all modules that receive warm reset.

Related Information

Reset Manager on page 3-1
For more information, refer to "Reset Sequencing" in the *Reset Manager* chapter.

Safe Mode

Safe mode is enabled in the HPS by the assertion of a safe mode request from the reset manager or by a cold reset. Assertion of the safe mode request from the reset manager sets the safe mode bit in the clock manager control register. No other control register bits are affected by the safe mode request from the reset manager.

When safe mode is enabled, the main PLL hardware-managed clocks (C0-C2) are bypassed to the `osc1_clk` clock and are directly generated from the `osc1_clk` clock. While in safe mode, clock manager register settings, which control clock behavior, are not changed. However, the hardware bypasses these settings and uses safe, default settings.

The hardware-managed clocks are forced to their safe mode values such that the following conditions occur:

- The hardware-managed clocks are bypassed to the `osc1_clk` clock, including counters in the main PLL.
- Programmable dividers select the reset default values.
- The flash controller clocks multiplexer selects the output from the peripheral PLL.
- All clocks are enabled.

A write by software is the only way to clear the safe mode bit (`safemode`) of the `ctrl` register.

Note: Before coming out of safe mode, all registers and clocks need to be configured correctly. It is possible to program the clock manager in such a way that only a cold reset can return the clocks to a functioning state. Altera strongly recommends using Altera-provided libraries to configure and control HPS clocks.

Interrupts

The clock manger provides one interrupt output, enabled using the interrupt enable register (`intren`). The source of the interrupt is six inputs, namely, an achieving lock and a losing lock bit in the interrupt status register (`inter`) for each PLL.

Clock Usage By Module

The following table lists every clock input generated by the clock manager to all modules in the HPS. System clock names are global for the entire HPS and system clocks with the same name are phase-aligned at all endpoints.

Table 2-9: Clock Usage By Module

Module Name	System Clock Name	Use
MPU subsystem	`mpu_clk`	Main clock for the MPU subsystem
	`mpu_periph_clk`	Clock for peripherals inside the MPU subsystem
	`dbg_at_clk`	Trace bus clock
	`dbg_clk`	Debug clock
	`mpu_l2_ram_clk`	Clock for the L2 cache and Accelerator Coherency Port (ACP) ID mapper
	`l4_mp_clk`	Clock for the ACP ID mapper control slave

Module Name	System Clock Name	Use
Interconnect	l3_main_clk	Clock for the L3 main switch
	dbg_at_clk	Clock for the System Trace Macrocell (STM) slave and Embedded Trace Router (ETR) master connections
	dbg_clk	Clock for the DAP master connection
	l3_mp_clk	Clock for the L3 master peripheral switch
	l4_mp_clk	Clock for the L4 MP bus, Secure Digital (SD) / MultiMediaCard (MMC) master, and EMAC masters
	usb_mp_clk	Clock for the USB masters and slaves
	nand_x_clk	Clock for the NAND master
	cfg_clk	Clock for the FPGA manager configuration data slave
	l3_sp_clk	Clock for the L3 slave peripheral switch
	l3_main_clk	Clock for the L4 SPIS bus master
	mpu_l2_ram_clk	Clock for the ACP ID mapper slave and L2 master connections
	osc1_clk	Clock for the L4 OSC1 bus master
	spi_m_clk	Clock for the L4 SPIM bus master
	l4_sp_clk	Clock for the L4 SP bus master
	l4_mp_clk	Clock for the quad SPI bus slave
Boot ROM	l3_main_clk	Clock for the boot ROM

Module Name	System Clock Name	Use
On-chip RAM	`l3_main_clk`	Clock for the on-chip RAM
DMA controller	`l4_main_clk`	Clock for the DMA
	`dbg_at_clk`	Clock synchronous to the STM module
	`l4_mp_clk`	Clock synchronous to the quad SPI flash
FPGA manager	`cfg_clk`	Clock for the control block (CB) data interface and configuration data slave
	`l4_mp_clk`	Clock for the control slave
HPS-to-FPGA bridge	`l3_main_clk`	Clock for the data slave
	`l4_mp_clk`	Clock for the global programmer's view (GPV) slave
FPGA-to-HPS bridge	`l3_main_clk`	Clock for the data master
	`l4_mp_clk`	Clock for the GPV slave
Lightweight HPS-to-FPGA bridge	`l4_mp_clk`	Clock for the GPV masters, and the data and GPV slave
Quad SPI flash controller	`l4_mp_clk`	Clock for the control slave
	`qspi_clk`	Reference clock for serialization
SD/MMC controller	`l4_mp_clk`	Clock for the master and slave
	`sdmmc_clk`	Clock for the SD/MMC internal logic

Module Name	System Clock Name	Use
EMAC 0	`l4_mp_clk`	Clock for the master
	`emac0_clk`	EMAC 0 internal logic clock
	`osc1_clk`	IEEE 1588 timestamp clock
EMAC 1	`l4_mp_clk`	Clock for the master
	`emac1_clk`	EMAC 1 internal logic clock
	`osc1_clk`	IEEE 1588 timestamp clock
USB 0	`usb_mp_clk`	Clock for the master and slave
USB 1	`usb_mp_clk`	Clock for the master and slave
NAND flash controller	`nand_x_clk`	NAND high-speed master and slave clock
	`nand_clk`	NAND flash clock
OSC1 timer 0	`osc1_clk`	Clock for the OSC1 timer 0
OSC1 timer 1	`osc1_clk`	Clock for the OSC1 timer 1
SP timer 0	`l4_sp_clk`	Clock for the SP timer 0
SP timer 1	`l4_sp_clk`	Clock for the SP timer 1
I^{2}C controller 0	`l4_sp_clk`	Clock for the I^{2}C 0
I^{2}C controller 1	`l4_sp_clk`	Clock for the I^{2}C 1
I^{2}C controller 2	`l4_sp_clk`	Clock for the I^{2}C 2
I^{2}C controller 3	`l4_sp_clk`	Clock for the I^{2}C 3

Module Name	System Clock Name	Use
UART controller 0	`l4_sp_clk`	Clock for the UART 0
UART controller 1	`l4_sp_clk`	Clock for the UART 1
CAN controller 0	`l4_sp_clk`	Clock for the slave
	`can0_clk`	CAN 0 controller clock
CAN controller 1	`l4_sp_clk`	Clock for the slave
	`can1_clk`	CAN 1 controller clock
GPIO interface 0	`l4_mp_clk`	Clock for the slave
	`gpio_db_clk`	Debounce clock
GPIO interface 1	`l4_mp_clk`	Clock for the slave
	`gpio_db_clk`	Debounce clock
GPIO interface 2	`l4_mp_clk`	Clock for the slave
	`gpio_db_clk`	Debounce clock
System manager	`osc1_clk`	Clock for the system manager

Module Name	System Clock Name	Use
SDRAM subsystem	`l4_sp_clk`	Clock for the control slave
	`ddr_dq_clk`	Off-chip data clock
	`ddr_dqs_clk`	Clock for the MPFE, single-port controller, CSRs, and PHY
	`ddr_2x_dqs_clk`	Off-chip strobe data clock
	`mpu_l2_ram_clk`	Clock for the slave connected to MPU subsystem L2 cache
	`l3_main_clk`	Clock for the slave connected to L3 interconnect
L4 watchdog timer 0	`osc1_clk`	Clock for the L4 watchdog timer 0
L4 watchdog timer 1	`osc1_clk`	Clock for the L4 watchdog timer 1
SPI master controller 0	`spi_m_clk`	Clock for the SPI master 0
SPI master controller 1	`spi_m_clk`	Clock for the SPI master 1
SPI slave controller 0	`l4_main_clk`	Clock for the SPI slave 0
SPI slave controller 1	`l4_main_clk`	Clock for the SPI slave 1
Debug subsystem	`l4_mp_clk`	System bus clock
	`dbg_clk`	Debug clock
	`dbg_at_clk`	Trace bus clock
	`dbg_trace_clk`	Trace port clock
Reset manager	`osc1_clk`	Clock for the reset manager
	`l4_sp_clk`	Clock for the slave

Module Name	System Clock Name	Use
Scan manager	`spi_m_clk`	Clock for the scan manager
Timestamp generator	`dbg_timer_clk`	Clock for the timestamp generator

Clock Manager Address Map and Register Definitions

The address map and register definitions for the HPS-FPGA bridge consist of the following regions:

ctrl Fields

Bit	Name	Description	Access	Reset
2	ensfmdwr	When set the Clock Manager will respond to a Safe Mode request from the Reset Manager on a warm reset by setting the Safe Mode bit. When clear the clock manager will not set the the Safe Mode bit on a warm reset This bit is cleared on a cold reset. Warm reset has no affect on this bit.	RW	0x1
0	safemode	When set the Clock Manager is in Safe Mode. In Safe Mode Clock Manager register settings defining clock behavior are ignored and clocks are set to a Safe Mode state.In Safe Mode all clocks with the optional exception of debug clocks, are directly generated from the EOSC1 clock input, all PLLs are bypassed, all programmable dividers are set to 1 and all clocks are enabled. This bit should only be cleared when clocks have been correctly configured This field is set on a cold reset and optionally on a warm reset and may not be set by SW.	RW	0x1

bypass

Contains fields that control bypassing each PLL.

Module Instance	Base Address	Register Address

Reserved															busy RO 0x0

stat Fields

Bit	Name	Description	Access	Reset
0	busy	This read only bit indicates that the Hardware Managed clock's state machine is active. If the state machine is active, then the clocks are in transition. Software should poll this bit after changing the source of internal clocks when writing to the BYPASS, CTRL or DBCTRL registers. Immediately following writes to any of these registers, SW should wait until this bit is IDLE before proceeding with any other register writes in the Clock Manager. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit. **Value** — **Description** 0x0 — Clocks stable 0x1 — Clocks in transition	RO	0x0

Main PLL Group Register Descriptions

Contains registers with settings for the Main PLL.

Offset: `0x40`

vco on page 2-32
Contains settings that control the Main PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). The VCO input clock source is always eosc1_clk. Fields are only reset by a cold reset.

misc on page 2-34
Contains VCO control signals and other PLL control signals need to be controllable through register. Fields are only reset by a cold reset.

mpuclk on page 2-35
Contains settings that control clock mpu_clk generated from the C0 output of the Main PLL. Only reset by a cold reset.

mainclk on page 2-35
Contains settings that control clock main_clk generated from the C1 output of the Main PLL. Only reset by a cold reset.

dbgatclk on page 2-36
Contains settings that control clock dbg_base_clk generated from the C2 output of the Main PLL. Only reset by a cold reset.

mainqspiclk on page 2-36
Contains settings that control clock main_qspi_clk generated from the C3 output of the Main PLL. Only reset by a cold reset.

mainnandsdmmcclk on page 2-37
Contains settings that control clock main_nand_sdmmc_clk generated from the C4 output of the Main PLL. Only reset by a cold reset.

cfgs2fuser0clk on page 2-37
Contains settings that control clock cfg_s2f_user0_clk generated from the C5 output of the Main PLL. Qsys and user documenation refer to cfg_s2f_user0_clk as cfg_h2f_user0_clk. Only reset by a cold reset.

en on page 2-38
Contains fields that control clock enables for clocks derived from the Main PLL. 1: The clock is enabled. 0: The clock is disabled. Fields are only reset by a cold reset.

maindiv on page 2-39
Contains fields that control clock dividers for main clocks derived from the Main PLL Fields are only reset by a cold reset.

dbgdiv on page 2-40
Contains fields that control clock dividers for debug clocks derived from the Main PLL Fields are only reset by a cold reset.

tracediv on page 2-41
Contains a field that controls the clock divider for the debug trace clock derived from the Main PLL Only reset by a cold reset.

l4src on page 2-42
Contains fields that select the clock source for L4 MP and SP APB interconnect Fields are only reset by a cold reset.

stat on page 2-43
Contains Output Clock Counter Reset acknowledge status.

vco

Contains settings that control the Main PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). The VCO input clock source is always eosc1_clk. Fields are only reset by a cold reset.

RW 0x1</td><td>pwrdn
RW 0x1</td><td>en
RW 0x0</td><td>bgpwrdn
RW 0x1</td></tr>
</table>

vco Fields

Bit	Name	Description	Access	Reset
31	regextsel	If set to '1', the external regulator is selected for the PLL. If set to '0', the internal regulator is slected. It is strongly recommended to select the external regulator while the PLL is not enabled (in reset), and then disable the external regulater once the PLL becomes enabled. Software should simulateously update the 'Enable' bit and the 'External Regulator Input Select' in the same write access to the VCO register. When the 'Enable' bit is clear, the 'External Regulator Input Select' should be set, and vice versa. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x1
30:25	outreset	Resets the individual PLL output counter. For software to change the PLL output counter without producing glitches on the respective clock, SW must set the VCO register respective Output Counter Reset bit. Software then polls the respective Output Counter Reset Acknowledge bit in the Output Counter Reset Ack Status Register. Software then writes the appropriate counter register, and then clears the respective VCO register Output Counter Reset bit. LSB 'outreset[0]' corresponds to PLL output clock C0, etc. If set to '1', reset output divider, no clock output from counter. If set to '0', counter is not reset. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x0
24	outresetall	Before releasing Bypass, All Output Counter Reset must be set and cleared by software for correct clock operation. If '1', Reset phase multiplexer and all output counter state. So that after the assertion all the clocks output are start from rising edge align. If '0', phase multiplexer and output counter state not reset and no change to the phase of the clock outputs.	RW	0x0
21:16	denom	Denominator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1
15:3	numer	Numerator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1

Bit	Name	Description	Access	Reset
2	pwrdn	If '1', power down analog circuitry. If '0', analog circuitry not powered down.	RW	0x1
1	en	If '1', VCO is enabled. If '0', VCO is in reset.	RW	0x0
0	bgpwrdn	If '1', powers down bandgap. If '0', bandgap is not power down.	RW	0x1

misc

Contains VCO control signals and other PLL control signals need to be controllable through register. Fields are only reset by a cold reset.

stat Fields

Bit	Name	Description	Access	Reset
5:0	`outresetack`	These read only bits per PLL output indicate that the PLL has received the Output Reset Counter request and has gracefully stopped the respective PLL output clock. For software to change the PLL output counter without producing glitches on the respective clock, SW must set the VCO register respective Output Counter Reset bit. Software then polls the respective Output Counter Reset Acknowledge bit in the Output Counter Reset Ack Status Register. Software then writes the appropriate counter register, and then clears the respective VCO register Output Counter Reset bit. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit. **Value** **Description** 0x0 Idle 0x1 Output Counter Acknowledge received.	RO	0x0

Peripheral PLL Group Register Descriptions

Contains registers with settings for the Peripheral PLL.

Offset: `0x80`

vco on page 2-45
Contains settings that control the Peripheral PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). Fields are only reset by a cold reset.

misc on page 2-47
Contains VCO control signals and other PLL control signals need to be controllable through register. Fields are only reset by a cold reset.

emac0clk on page 2-47
Contains settings that control clock emac0_clk generated from the C0 output of the Peripheral PLL. Only reset by a cold reset.

emac1clk on page 2-48
Contains settings that control clock emac1_clk generated from the C1 output of the Peripheral PLL. Only reset by a cold reset.

perqspiclk on page 2-48
Contains settings that control clock periph_qspi_clk generated from the C2 output of the Peripheral PLL. Only reset by a cold reset.

pernandsdmmcclk on page 2-49
Contains settings that control clock periph_nand_sdmmc_clk generated from the C3 output of the Peripheral PLL. Only reset by a cold reset.

perbaseclk on page 2-49
Contains settings that control clock periph_base_clk generated from the C4 output of the Peripheral PLL. Only reset by a cold reset.

s2fuser1clk on page 2-50
Contains settings that control clock s2f_user1_clk generated from the C5 output of the Peripheral PLL. Qsys and user documenation refer to s2f_user1_clk as h2f_user1_clk. Only reset by a cold reset.

en on page 2-50
Contains fields that control clock enables for clocks derived from the Peripheral PLL 1: The clock is enabled. 0: The clock is disabled. Fields are only reset by a cold reset.

div on page 2-52
Contains fields that control clock dividers for clocks derived from the Peripheral PLL Fields are only reset by a cold reset.

gpiodiv on page 2-54
Contains a field that controls the clock divider for the GPIO De-bounce clock. Only reset by a cold reset.

src on page 2-54
Contains fields that select the source clocks for the flash controllers. Fields are only reset by a cold reset.

stat on page 2-56
Contains Output Clock Counter Reset acknowledge status.

vco

Contains settings that control the Peripheral PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). Fields are only reset by a cold reset.

vco Fields

Bit	Name	Description	Access	Reset
31	`regextsel`	If set to '1', the external regulator is selected for the PLL. If set to '0', the internal regulator is slected. It is strongly recommended to select the external regulator while the PLL is not enabled (in reset), and then disable the external regulater once the PLL becomes enabled. Software should simulateously update the 'Enable' bit and the 'External Regulator Input Select' in the same write access to the VCO register. When the 'Enable' bit is clear, the 'External Regulator Input Select' should be set, and vice versa. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x1

Bit	Name	Description	Access	Reset
30:25	outreset	Resets the individual PLL output counter. For software to change the PLL output counter without producing glitches on the respective clock, SW must set the VCO register respective Output Counter Reset bit. Software then polls the respective Output Counter Reset Acknowledge bit in the Output Counter Reset Ack Status Register. Software then writes the appropriate counter register, and then clears the respective VCO register Output Counter Reset bit. LSB 'outreset[0]' corresponds to PLL output clock C0, etc. If set to '1', reset output divider, no clock output from counter. If set to '0', counter is not reset. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x0
24	outresetall	Before releasing Bypass, All Output Counter Reset must be set and cleared by software for correct clock operation. If '1', Reset phase multiplexer and all output counter state. So that after the assertion all the clocks output are start from rising edge align. If '0', phase multiplexer and output counter state not reset and no change to the phase of the clock outputs.	RW	0x0
23:22	psrc	Controls the VCO input clock source. Qsys and user documenation refer to f2s_periph_ref_clk as f2h_periph_ref_clk. **Value** — **Description** 0x0 — eosc1_clk 0x1 — eosc2_clk 0x2 — f2s_periph_ref_clk	RW	0x0
21:16	denom	Denominator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1
15:3	numer	Numerator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1
2	pwrdn	If '1', power down analog circuitry. If '0', analog circuitry not powered down.	RW	0x1

Bit	Name	Description	Access	Reset
1	en	If '1', VCO is enabled. If '0', VCO is in reset.	RW	0x0
0	bgpwrdn	If '1', powers down bandgap. If '0', bandgap is not power down.	RW	0x1

misc

Contains VCO control signals and other PLL control signals need to be controllable through register. Fields are only reset by a cold reset.

Bit	Name	Description	Access	Reset
5:0	outresetack	These read only bits per PLL output indicate that the PLL has received the Output Reset Counter request and has gracefully stopped the respective PLL output clock. For software to change the PLL output counter without producing glitches on the respective clock, SW must set the VCO register respective Output Counter Reset bit. Software then polls the respective Output Counter Reset Acknowledge bit in the Output Counter Reset Ack Status Register. Software then writes the appropriate counter register, and then clears the respective VCO register Output Counter Reset bit. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit. **Value** **Description** 0x0 Idle 0x1 Output Counter Acknowledge received.	RO	0x0

SDRAM PLL Group Register Descriptions

Contains registers with settings for the SDRAM PLL.

Offset: 0xc0

vco on page 2-57
Contains settings that control the SDRAM PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). Fields are only reset by a cold reset.

ctrl on page 2-59
Contains VCO control signals and other PLL control signals need to be controllable through register. Fields are only reset by a cold reset.

ddrdqsclk on page 2-60
Contains settings that control clock ddr_dqs_clk generated from the C0 output of the SDRAM PLL. Fields are only reset by a cold reset.

ddr2xdqsclk on page 2-61
Contains settings that control clock ddr_2x_dqs_clk generated from the C1 output of the SDRAM PLL. Fields are only reset by a cold reset.

ddrdqclk on page 2-61
Contains settings that control clock ddr_dq_clk generated from the C2 output of the SDRAM PLL. Fields are only reset by a cold reset.

s2fuser2clk on page 2-62
Contains settings that control clock s2f_user2_clk generated from the C5 output of the SDRAM PLL. Qsys and user documenation refer to s2f_user2_clk as h2f_user2_clk Fields are only reset by a cold reset.

en on page 2-63
Contains fields that control the SDRAM Clock Group enables generated from the SDRAM PLL clock outputs. 1: The clock is enabled. 0: The clock is disabled. Fields are only reset by a cold reset.

stat on page 2-64
Contains Output Clock Counter Reset acknowledge status.

vco

Contains settings that control the SDRAM PLL VCO. The VCO output frequency is the input frequency multiplied by the numerator (M+1) and divided by the denominator (N+1). Fields are only reset by a cold reset.

vco Fields

Bit	Name	Description	Access	Reset
31	`regextsel`	If set to '1', the external regulator is selected for the PLL. If set to '0', the internal regulator is slected. It is strongly recommended to select the external regulator while the PLL is not enabled (in reset), and then disable the external regulater once the PLL becomes enabled. Software should simulateously update the 'Enable' bit and the 'External Regulator Input Select' in the same write access to the VCO register. When the 'Enable' bit is clear, the 'External Regulator Input Select' should be set, and vice versa. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x1
30:25	`outreset`	Resets the individual PLL output counter. For software to change the PLL output counter without producing glitches on the respective clock, SW must set the VCO register respective Output Counter Reset bit. Software then polls the respective Output Counter Reset Acknowledge bit in the Output Counter Reset Ack Status Register. Software then writes the appropriate counter register, and then clears the respective VCO register Output Counter Reset bit. LSB 'outreset[0]' corresponds to PLL output clock C0, etc. If set to '1', reset output divider, no clock output from counter. If set to '0', counter is not reset. The reset value of this bit is applied on a cold reset; warm reset has no affect on this bit.	RW	0x0
24	`outresetall`	Before releasing Bypass, All Output Counter Reset must be set and cleared by software for correct clock operation. If '1', Reset phase multiplexer and output counter state. So that after the assertion all the clocks output are start from rising edge align. If '0', phase multiplexer and output counter state not reset and no change to the phase of the clock outputs.	RW	0x0
23:22	`ssrc`	Controls the VCO input clock source. The PLL must by bypassed to eosc1_clk before changing this field. Qsys and user documenation refer to f2s_sdram_ref_clk as f2h_sdram_ref_clk. **Value** **Description** 0x0 eosc1_clk 0x1 eosc2_clk 0x2 f2s_sdram_ref_clk	RW	0x0

Bit	Name	Description	Access	Reset
21:16	denom	Denominator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1
15:3	numer	Numerator in VCO output frequency equation. For incremental frequency change, if the new value lead to less than 20% of the frequency change, this value can be changed without resetting the PLL. The Numerator and Denominator can not be changed at the same time for incremental frequency changed.	RW	0x1
2	pwrdn	If '1', power down analog circuitry. If '0', analog circuitry not powered down.	RW	0x1
1	en	If '1', VCO is enabled. If '0', VCO is in reset.	RW	0x0
0	bgpwrdn	If '1', powers down bandgap. If '0', bandgap is not power down.	RW	0x1

Document Revision History

Table 2-10: Document Revision History

Date	Version	Changes
June 2014	2014.06.30	E0SC1 changed to HPS_CLK1 E0SC2 changed to HPS_CLK2 Added Address Map and Register Descriptions
February 2014	2014.02.28	Updated content in the "Peripheral Clock Group" section
December 2013	2013.12.30	Minor formatting updates.
November 2012	1.2	Minor updates.
May 2012	1.1	• Reorganized and expanded functional description section. • Added address map and register definitions section.
January 2012	1.0	Initial release.

Reset Manager 3

2014.06.30

cv_54003 Subscribe Send Feedback

The reset manager generates module reset signals based on reset requests from the various sources in the HPS and FPGA fabric, and software writing to the module-reset control registers. The reset manager ensures that a reset request from the FPGA fabric can occur only after the FPGA portion of the system-on-a-chip (SoC) device is configured.

The HPS contains three reset domains. Each reset domain can be reset independently. Each register in the HPS that can be reset belongs to one particular reset domain.

Table 3-1: HPS Reset Domains

Domain Name	Domain Logic
TAP	JTAG test access port (TAP) controller, which is used by the debug access port (DAP).
Debug	All debug logic including most of the DAP, CoreSight™ components connected to the debug peripheral bus, trace, the microprocessor unit (MPU) subsystem, and the FPGA fabric.
System	All HPS logic except what is in the TAP and debug reset domains. Includes nondebug logic in the FPGA fabric connected to the HPS reset signals.

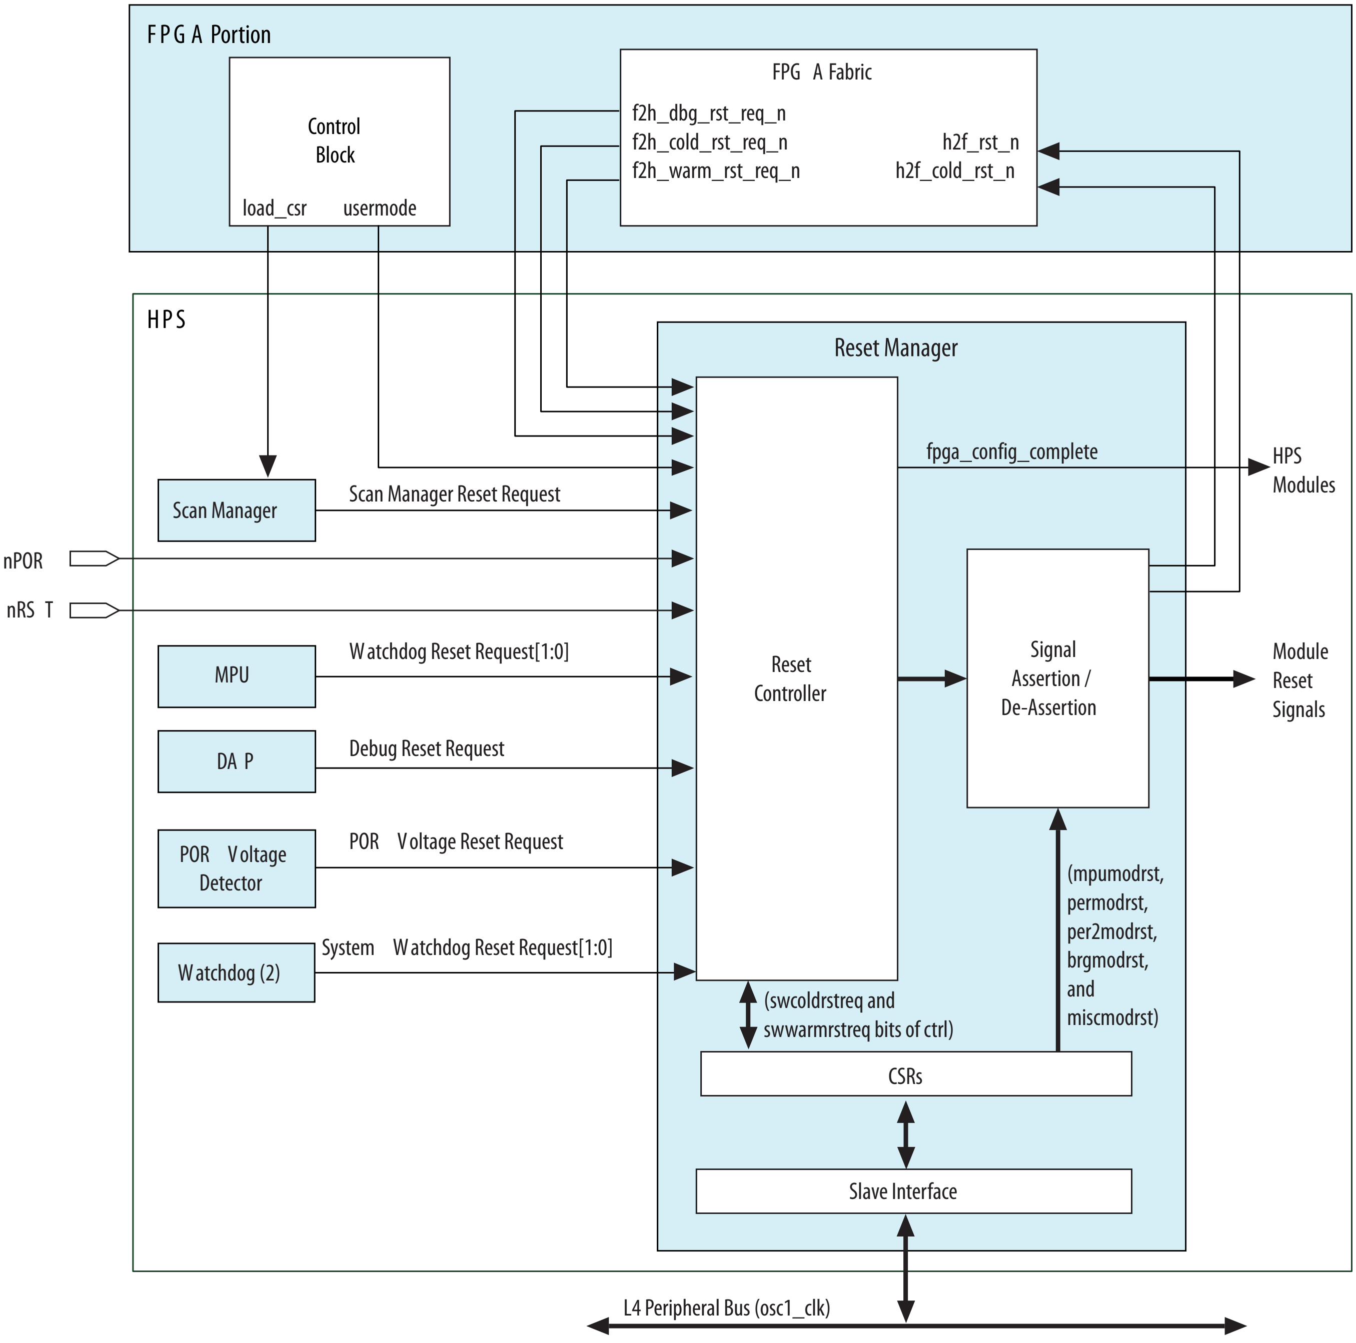
The HPS supports the following reset types:

- Cold reset (power-on reset)
  - Used to ensure the HPS is placed in a default state sufficient for software to boot
  - Triggered by a power-on reset and other sources
  - Resets all HPS logic that can be reset
  - Affects all reset domains
- Warm reset
  - Occurs after HPS has already completed a cold reset
  - Used to recover system from a non-responsive condition
  - Resets a subset of the HPS state reset by a cold reset
  - Only affects the system reset domain, which allows debugging (including trace) to operate through the warm reset
- Debug reset
  - Occurs after HPS has already been through a cold reset
  - Used to recover debug logic from a non-responsive condition
  - Only affects the debug reset domain

Reset Manager Block Diagram and System Integration

Figure 3-1: Reset Manager Block Diagram

The following figure shows a block diagram of the reset manager in the SoC device. For clarity, reset-related handshaking signals to other HPS modules and to the clock manager module are omitted.



HPS External Reset Sources

The following table lists the reset sources external to the HPS. All signals are synchronous to the osc1_clk clock. The reset signals from the HPS to the FPGA fabric must be synchronized to your user logic clock domain.

Table 3-2: HPS External Reset Sources

Source	Description
f2h_cold_rst_req_n	Cold reset request from FPGA fabric (active low)
f2h_warm_rst_req_n	Warm reset request from FPGA fabric (active low)
f2h_dbg_rst_req_n	Debug reset request from FPGA fabric (active low)
h2f_cold_rst_n	Cold-only reset to FPGA fabric (active low)
h2f_rst_n	Cold or warm reset to FPGA fabric (active low)
h2f_dbg_rst_n	Debug reset (dbg_rst_n) to FPGA fabric (active low)
load_csr	Cold-only reset from FPGA control block (CB) and scan manager
nPOR	Power-on reset pin (active low)
nRST	Warm reset pin (active low)

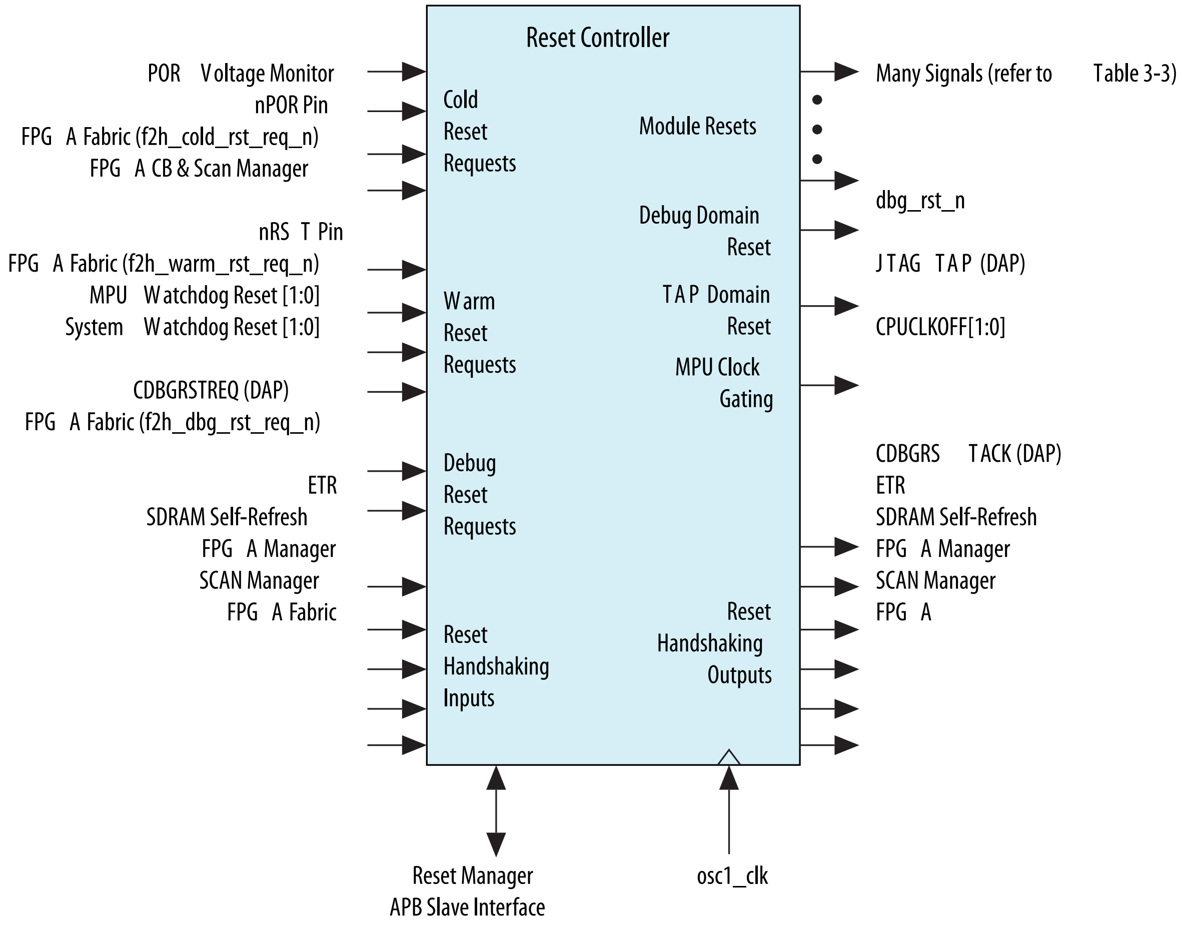
Reset Controller

The reset controller performs the following functions:

- Accepts reset requests from the FPGA CB, FPGA fabric, modules in the HPS, and reset pins
- Generates an individual reset signal for each module instance for all modules in the HPS
- Provides reset handshaking signals to support system reset behavior

The reset controller generates module reset signals from external reset requests and internal reset requests. External reset requests originate from sources external to the reset manager. Internal reset requests originate from control registers in the reset manager.

Figure 3-2: Reset Controller Signals



The reset controller supports the following cold reset requests:

- Power-on reset (POR) voltage monitor
- Cold reset request pin (nPOR)
- FPGA fabric
- FPGA CB and scan manager
- Software cold reset request bit (swcoldrstreq) of the control register (ctrl)

The reset controller supports the following warm reset requests:

- Warm reset request pin (nRST)
- FPGA fabric
- Software warm reset request bit (swwarmrstreq) of the ctrl register
- MPU watchdog reset requests for CPU0 and CPU1
- System watchdog timer 0 and 1 reset requests

The reset controller supports the following debug reset requests:

- CDBGRSTREQ from DAP
- FPGA fabric

Module Reset Signals

The following tables list the module reset signals. The module reset signals are organized in groups for the MPU, peripherals, bridges, the level 3 (L3) interconnect, and miscellaneous.

In the following tables, columns marked for Cold Reset, Warm Reset, and Debug Reset denote reset signals asserted by each type of reset. For example, writing a 1 to the swwarmrstreq bit in the ctrl register resets all the modules that have a checkmark in the Warm Reset column.

The column marked for Software Deassert denotes reset signals that are left asserted by the reset manager. To activate the related modules, software can deassert these reset signals as needed by writing to the following reset manager registers:

- MPU module reset register (mpumodrst)
- Peripheral module reset register (permodrst)
- Peripheral 2 module reset register (per2modrst)
- Bridge module reset register (brgmodrst)

Table 3-3: MPU Group, Generated Module Resets

Module Reset Signal	Description	Reset Domain	Cold Reset	Warm Reset	Debug Reset	Software Deassert
mpu_cpu_rst_n[0]	Resets each processor in the MPU	System	X	X		
mpu_cpu_rst_n[1]	Resets each processor in the MPU	System	X	X		X
mpu_wd_rst_n	Resets both per-processor watchdogs in the MPU	System	X	X

Module Reset Signal	Description	Reset Domain	Cold Reset	Warm Reset	Debug Reset	Software Deassert
`l3_rst_n`	Resets L3 interconnect and L4 buses	System	X	X		

Slave Interface and Status Register

The reset manager slave interface is used to control and monitor the reset states.

The status register (`stat`) in the reset manager contains the status of the reset requester. The register contains a bit for each reset request. The `stat` register captures all reset requests that have occurred. Software is responsible for clearing the bits.

Functional Description of the Reset Manager

The reset manager generates reset signals to modules in the HPS and to the FPGA fabric. The following actions generate reset signals:

- Software writing a 1 to the `swcoldrstreq` or `swwarmrstreq` bits in the `ctrl` register. Writing either bit causes the reset controller to perform a reset sequence.
- Software writing to the `mpumodrst`, `permodrst`, `per2modrst`, `brgmodrst`, or `miscmodrst` module reset control registers.
- Asserting reset request signals triggers the reset controller. All external reset requests cause the reset controller to perform a reset sequence.

Multiple reset requests can be driven to the reset manager at the same time. Cold reset requests take priority over warm and debug reset requests. Higher priority reset requests preempt lower priority reset requests. There is no priority difference among reset requests within the same domain.

If a cold reset request is issued while another cold reset is already underway, the reset manager extends the reset period for all the module reset outputs until all cold reset requests are removed. If a cold reset request is issued while the reset manager is removing other modules out of the reset state, the reset manager returns those modules back to the reset state.

If a warm reset request is issued while another warm reset is already underway, the first warm reset completes before the second warm reset begins. If the second warm reset request is removed before the first warm reset completes, the warm first reset is extended to meet the timing requirements of the second warm reset request.

The `nPOR` pin can be used to extend the cold reset beyond what the POR voltage monitor automatically provides. The use of the `nPOR` pin is optional and can be tied high when it is not required.

For information regarding HPS power supply operating conditions, refer to the device datasheet.

Related Information

For information about the required duration of reset request signal assertion, refer to the Cyclone V Device Datasheet.

Reset Sequencing

The reset controller sequences resets without software assistance. Module reset signals are asserted asynchronously at the same time. The reset manager deasserts the module reset signals synchronous to the `osc1_clk` clock. Module reset signals are deasserted in groups in a fixed sequence. All module reset signals in a group are deasserted at the same time.

The reset manager sends a safe mode request to the clock manager to put the clock manager in safe mode, which creates a fixed and known relationship between the `osc1_clk` clock and all other clocks generated by the clock manager.

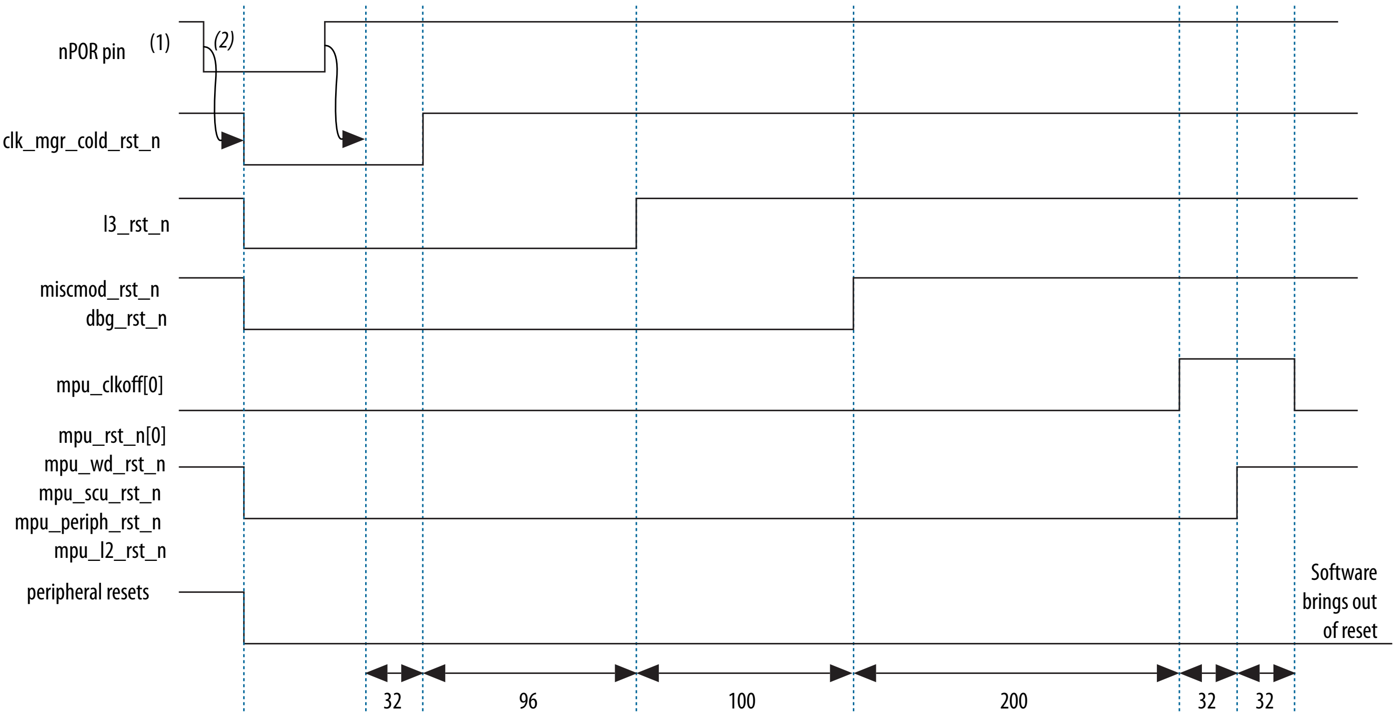
After the reset manager releases the MPU subsystem from reset, CPU1 is left in reset and CPU0 begins executing code from the reset vector address. Software is responsible for deasserting CPU1 and other resets, as shown in MPU Group, Generated Module Resets Table. Software deasserts resets by writing the `mpumodrst`, `permodrst`, `per2modrst`, `brgmodrst`, and `miscmodrst` module-reset control registers.

Software can also bypass the reset controller and generate reset signals directly through the module-reset control registers. In this case, software is responsible for asserting module reset signals, driving them for the appropriate duration, and deasserting them in the correct order. The clock manager is not typically in safe mode during this time, so software is responsible for knowing the relationship between the clocks generated by the clock manager. Software must not assert a module reset signal that would prevent software from deasserting the module reset signal. For example, software should not assert the module reset to the processor executing the software.

Table 3-9: Minimum Pulse Width

Reset Type	Value
Warm Reset	6 `osc1_clk` cycles
Cold Reset	6 `osc1_clk` cycles

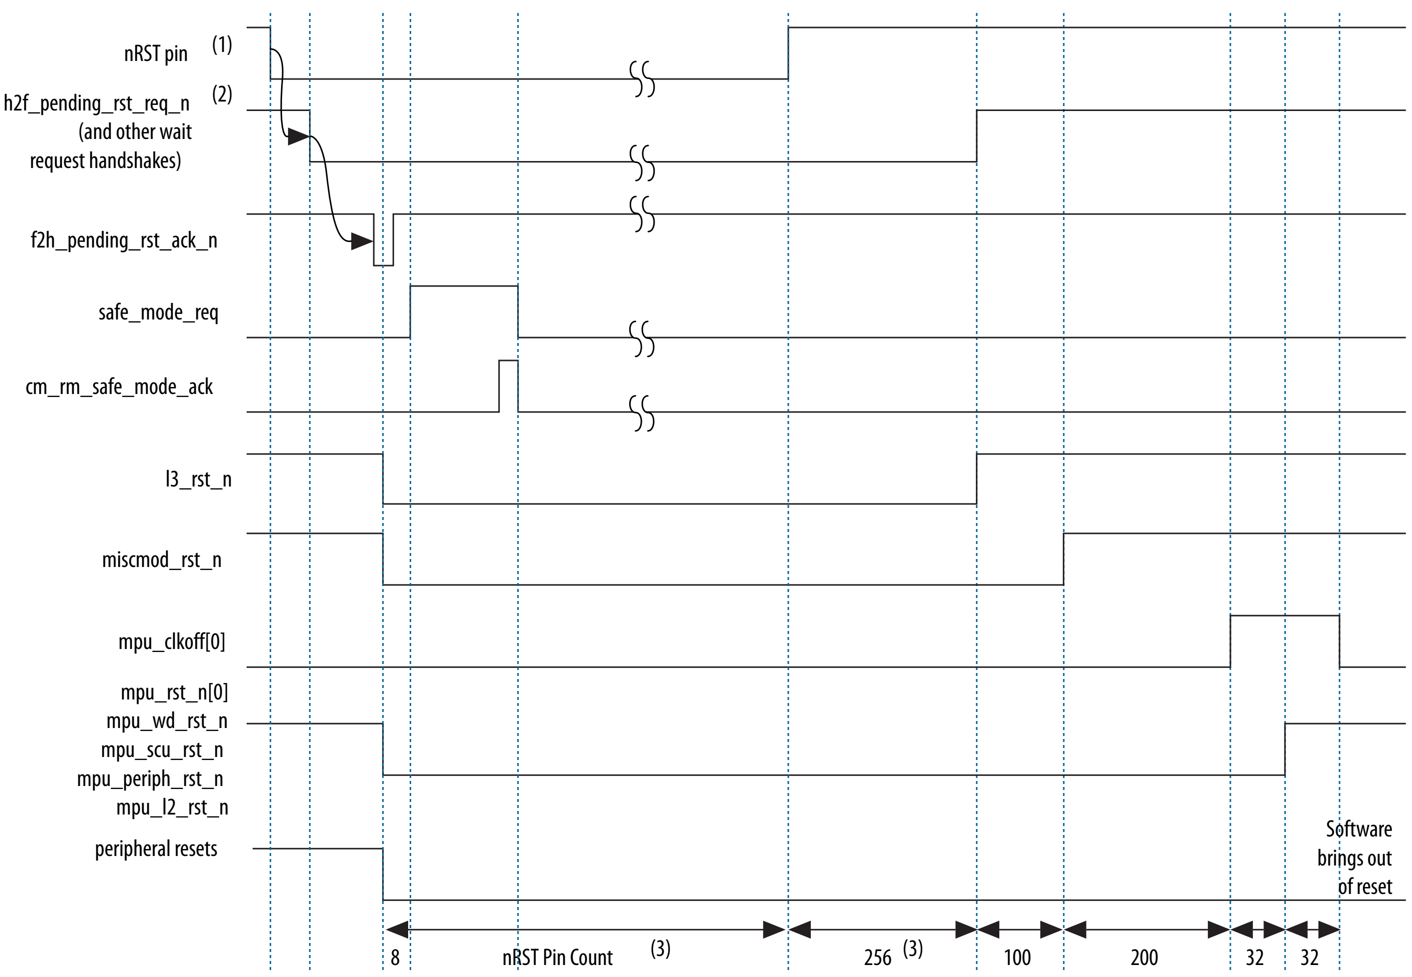
Figure 3-3: Cold Reset Timing Diagram



(1) Cold reset can be initiated from several other sources: FPGA CB, FPGA fabric, modules in the HPS, and reset pins.

(2) This dependency applies to all the reset signals.

Figure 3-4: Warm Reset Timing Diagram



(1) Cold reset can be initiated from several other sources: FPGA CB, FPGA fabric, modules in the HPS, and reset pins.

(2) When the nRSTpin count is zero, the 256 cycle stretch count is skipped and the start of the deassertion sequence is determined by the safe mode acknowledge signal or the userreleasing the warm reset button, whichever occurs later.

The cold and warm reset sequences consist of different reset assertion sequences and the same deassertion sequence. The following sections describe the sequences.

Note: Cold and Warm reset affect only the cpu0 and by default cpu1 is held in reset until the software running in the cpu0 releases it.

For more information about safe mode, refer to the *Clock Manager* chapter.

Cold Reset Assertion Sequence

The following list describes the assertion steps for cold reset shown in the cold Reset Timing Diagram:

1. Assert module resets.
2. Wait for 32 cycles. Deassert clock manager cold reset.
3. Wait for 96 cycles (so clocks can stabilize).
4. Proceed to the "Cold and Warm Reset Deassertion Sequence" section using the following link.

Related Information

Cold and Warm Reset Deassertion Sequence on page 3-13

Warm Reset Assertion Sequence

The following list describes the assertion steps for warm reset shown in the Warm Reset Timing Diagram:

1. Optionally, handshake with the embedded trace router (ETR) and wait for acknowledge.
2. Optionally, handshake with the FPGA fabric and wait for acknowledge.
3. Optionally, handshake with the SDRAM controller, scan manager, and FPGA manager, and wait for acknowledges.
4. Assert module resets (except the MPU watchdog timer resets when the MPU watchdog timers are the only request sources).
5. Wait for 8 cycles and send a safe mode request to the clock manager.
6. Wait for the greater of the `nRST` pin count + 256 stretch count, or the warm reset counter, or the clock manager safe mode acknowledge, then deassert all handshakes except warm reset ETR handshake (which is deasserted by software).
7. Proceed to the "Cold and Warm Reset Deassertion Sequence" section using the following link.

Note: The HPS_nRST is a bidirectional signal that is driven out when a warm reset is generated in the chip.

Related Information

Cold and Warm Reset Deassertion Sequence on page 3-13

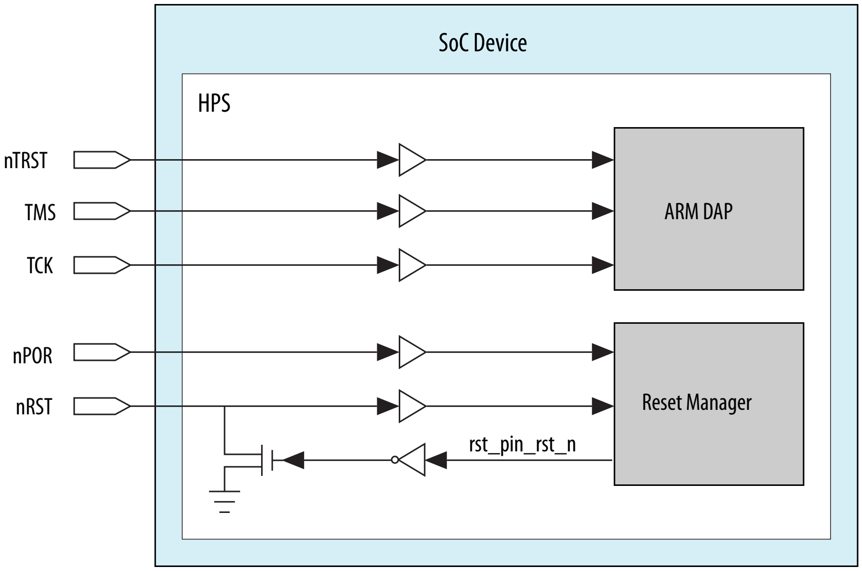
Cold and Warm Reset Deassertion Sequence

The following list describes the deassertion steps for both cold and warm reset shown in the Cold Reset Timing Diagram and Warm Reset Timing Diagram:

1. Deassert L3 reset.
2. Wait for 100 cycles. Deassert resets for miscellaneous-type and debug (cold only) modules.
3. Wait for 200 cycles. Assert `mpu_clkoff` for CPU0 and CPU1.
4. Wait for 32 cycles. Deassert resets for MPU modules.
5. Wait for 32 cycles. Deassert `mpu_clkoff` for CPU0 and CPU1.
6. Peripherals remain held in reset until software brings them out of reset.

Reset Pins

Figure 3-5: Reset Pins



The test reset (nTRST), test mode select (TMS), and test clock (TCK) pins are associated with the TAP reset domain and are used to reset the TAP controller in the DAP. These pins are not connected to the reset manager.

The nPOR and nRST pins are used to request cold and warm resets respectively. The nRST pin is an open drain output as well. Any warm reset request causes the reset manager to drive the rst_pin_rst_n signal output low, which drives the nRST pin low. The amount of time the reset manager pulls nRST low is controlled by the nRST pin count field (nrstcnt) of the reset cycles count register (counts). This technique can be used to reset external devices (such as external memories) connected to the HPS.

Reset Effects

The following list describes how reset affects HPS logic:

- The TAP reset domain ignores warm reset.
- The debug reset domain ignores warm reset.
- System reset domain cold resets ignore warm reset.
- Each module defines reset behavior individually.

Altering Warm Reset System Response

Registers in the clock manager, system manager, and reset manager control how warm reset affects the HPS. You can control the impact of a warm reset on the clocks and I/O elements.

Altera strongly recommends using Altera-provided libraries to configure and control this functionality.

The default warm reset behavior takes all clocks and I/O elements through a cold reset response. As your software becomes more stable or for debug purposes, you can alter the system response to a warm reset. The following suggestions provide ways to alter the system response to a warm reset. None of the register bits that control these items are affected by warm reset.

- Boot from on-chip RAM—enables warm boot from on-chip RAM instead of the boot ROM. When enabled, the boot ROM code validates the RAM code and jumps to it, making no changes to clocks or any other system settings prior to executing user code from on-chip RAM.
- Disable safe mode on warm reset—allows software to transition through a warm reset without affecting the clocks. Because the boot ROM code indirectly configures the clock settings after warm reset, Altera recommends to only disable safe mode when the HPS is not booting from a flash device.
- Disable safe mode on warm reset for the debug clocks—keeps the debug clocks from being affected by the assertion of safe mode request on a warm reset. This technique allows fast debug clocks, such as trace, to continue running through a warm reset. When enabled, the clock manager puts the debug clocks to their safe frequencies to respond to a safe mode request from the reset manager on a warm reset. Disable safe mode on warm reset for the debug clocks only when you are running the debug clocks off the main PLL VCO and you are certain the main PLL cannot be impacted by the event which caused the warm reset.
- Use the `osc1_clk` clock for debug control—keeps the debug base clock (main PLL C2 output) always bypassed to the `osc1_clk` external clock, independent of other clock manager settings. When implemented, disabling safe mode on warm reset for the debug clocks has no effect.

Related Information

Clock Manager on page 2-1
For more information about safe mode, refer to the *Clock Manager* chapter.

Reset Handshaking

The reset manager participates in several reset handshaking protocols to ensure other modules are safely reset.

Before issuing a warm reset, the reset manager performs a handshake with several modules to allow them to prepare for a warm reset. The handshake logic ensures the following conditions:

- ETR master has no pending master transactions to the L3 interconnect
- Optionally preserve SDRAM contents during warm reset by issuing self-refresh mode request
- FPGA manager stops generating configuration clock
- Scan manager stops generating JTAG and I/O configuration clocks
- Warns the FPGA fabric of the forthcoming warm reset

Similarly, the handshake logic associated with ETR also occurs during the debug reset to ensure that the ETR master has no pending master transactions to the L3 interconnect before the debug reset is issued. This action ensures that when ETR undergoes a debug reset, the reset has no adverse effects on the system domain portion of the ETR.

Reset Manager Address Map and Register Definitions

The address map and register definitions for the HPS-FPGA bridge consist of the following regions:

stat

The STAT register contains bits that indicate the reset source or a timeout event. For reset sources, a field is 1 if its associated reset requester caused the reset. For timeout events, a field is 1 if its associated timeout occured as part of a hardware sequenced warm/debug reset. Software clears bits by writing them with a value of 1. Writes to bits with a value of 0 are ignored. After a cold reset is complete, all bits are reset to their reset value except for the bit(s) that indicate the source of the cold reset. If multiple cold reset requests overlap with each other, the source de-asserts the request last will be logged. The other reset request source(s) de-assert the request in the same cycle will also be logged, the rest of the fields are reset to default value of 0. After a warm reset is complete, the bit(s) that indicate the source of the warm reset are set to 1. A warm reset doesn't clear any of the bits in the STAT register; these bits must be cleared by software writing the STAT register.

ctrl

The CTRL register is used by software to control reset behavior.It includes fields for software to initiate the cold and warm reset, enable hardware handshake with other modules before warm reset, and perform software handshake. The software handshake sequence must match the hardware sequence. Software mustde-assert the handshake request after asserting warm reset and before de-assert the warm reset. Fields are only reset by a cold reset.

ctrl Fields

Bit	Name	Description	Access	Reset
23	etrstallwarmrst	If a warm reset occurs and ETRSTALLEN is 1, hardware sets this bit to 1 to indicate that the stall of the ETR AXI master is pending. Hardware leaves the ETR stalled until software clears this field by writing it with 1. Software must only clear this field when it is ready to have the ETR AXI master start making AXI requests to write trace data.	RW	0x0
22	etrstallack	This is the acknowlege for a ETR AXI master stall initiated by the ETRSTALLREQ field. A 1 indicates that the ETR has stalled its AXI master	RO	0x0

Bit	Name	Description	Access	Reset
21	`etrstallreq`	Software writes this field 1 to request to the ETR that it stalls its AXI master to the L3 Interconnect. Software waits for the ETRSTALLACK to be 1 and then writes this field to 0. Note that it is possible for the ETR to never assert ETRSTALLACK so software should timeout if ETRSTALLACK is never asserted.	RW	0x0
20	`etrstallen`	This field controls whether the ETR is requested to idle its AXI master interface (i.e. finish outstanding transactions and not initiate any more) to the L3 Interconnect before a warm or debug reset. If set to 1, the Reset Manager makes a request to the ETR to stall its AXI master and waits for it to finish any outstanding AXI transactions before a warm reset of the L3 Interconnect or a debug reset of the ETR. This stalling is required because the debug logic (including the ETR) is reset on a debug reset and the ETR AXI master is connected to the L3 Interconnect which is reset on a warm reset and these resets can happen independently.	RW	0x1
18	`fpgahsack`	This is the acknowlege (high active) that the FPGA handshake acknowledge has been received by Reset Manager.	RO	0x0
17	`fpgahsreq`	Software writes this field 1 to initiate handshake request to FPGA . Software waits for the FPGAHSACK to be active and then writes this field to 0. Note that it is possible for the FPGA to never assert FPGAHSACK so software should timeout in this case.	RW	0x0
16	`fpgahsen`	This field controls whether to perform handshake with FPGA before asserting warm reset. If set to 1, the Reset Manager makes a request to the FPGAbefore asserting warm reset signals. However if FPGA is already in warm reset state, the handshake is not performed. If set to 0, the handshake is not performed	RW	0x0
14	`scanmgrhsack`	This is the acknowlege (high active) that the SCAN manager has successfully idled its output clocks.	RO	0x0
13	`scanmgrhsreq`	Software writes this field 1 to request to the SCAN manager to idle its output clocks. Software waits for the SCANMGRHSACK to be 1 and then writes this field to 0. Note that it is possible for the Scan Manager to never assert SCANMGRHSACK (e.g. its input clock is disabled) so software should timeout in this case.	RW	0x0

Bit	Name	Description	Access	Reset
12	scanmgrhsen	Enables a handshake between the Reset Manager and Scan Manager before a warm reset. The handshake is used to warn the Scan Manager that a warm reset it coming so it can prepare for it. When the Scan Manager receives a warm reset handshake, the Scan Manager drives its output clocks to a quiescent state to avoid glitches. If set to 1, the Reset Manager makes a request to the Scan Managerbefore asserting warm reset signals. However if the Scan Manager is already in warm reset, the handshake is skipped. If set to 0, the handshake is skipped.	RW	0x0
10	fpgamgrhsack	This is the acknowlege (high active) that the FPGA manager has successfully idled its output clock.	RO	0x0
9	fpgamgrhsreq	Software writes this field 1 to request to the FPGA Manager to idle its output clock. Software waits for the FPGAMGRHSACK to be 1 and then writes this field to 0. Note that it is possible for the FPGA Manager to never assert FPGAMGRHSACK so software should timeout in this case.	RW	0x0
8	fpgamgrhsen	Enables a handshake between the Reset Manager and FPGA Manager before a warm reset. The handshake is used to warn the FPGA Manager that a warm reset it coming so it can prepare for it. When the FPGA Manager receives a warm reset handshake, the FPGA Manager drives its output clock to a quiescent state to avoid glitches. If set to 1, the Manager makes a request to the FPGA Managerbefore asserting warm reset signals. However if the FPGA Manager is already in warm reset, the handshake is skipped. If set to 0, the handshake is skipped.	RW	0x0
6	sdrselfreqack	This is the acknowlege for a SDRAM self-refresh mode request initiated by the SDRSELFREFREQ field. A 1 indicates that the SDRAM Controller Subsystem has put the SDRAM devices into self-refresh mode.	RO	0x0
5	sdrselfrefreq	Software writes this field 1 to request to the SDRAM Controller Subsystem that it puts the SDRAM devices into self-refresh mode. This is done to preserve SDRAM contents across a software warm reset. Software waits for the SDRSELFREFACK to be 1 and then writes this field to 0. Note that it is possible for the SDRAM Controller Subsystem to never assert SDRSELFREFACK so software should timeout if SDRSELFREFACK is never asserted.	RW	0x0

Bit	Name	Description	Access	Reset
4	`sdrselfrefen`	This field controls whether the contents of SDRAM devices survive a hardware sequenced warm reset. If set to 1, the Reset Manager makes a request to the SDRAM Controller Subsystem to put the SDRAM devices into self-refresh mode before asserting warm reset signals. However, if SDRAM is already in warm reset, Handshake with SDRAM is not performed.	RW	0x0
1	`swwarmrstreq`	This is a one-shot bit written by software to 1 to trigger a hardware sequenced warm reset. It always reads the value 0.	RW	0x0
0	`swcoldrstreq`	This is a one-shot bit written by software to 1 to trigger a cold reset. It always reads the value 0.	RW	0x0

counts

The COUNTS register is used by software to control reset behavior.It includes fields for software to control the behavior of the warm reset and nRST pin. Fields are only reset by a cold reset.

counts Fields

Bit	Name	Description	Access	Reset
27:8	`nrstcnt`	The Reset Manager pulls down the nRST pin on a warm reset for the number of cycles specified in this register. A value of 0x0 prevents the Reset Manager from pulling down the nRST pin.	RW	0x800
7:0	`warmrstcycles`	On a warm reset, the Reset Manager releases the reset to the Clock Manager, and then waits for the number of cycles specified in this register before releasing the rest of the hardware controlled resets. Value must be greater than 16.	RW	0x80

mpumodrst

The MPUMODRST register is used by software to trigger module resets (individual module reset signals). Software explicitly asserts and de-asserts module reset signals by writing bits in the appropriate *MODRST register. It is up to software to ensure module reset signals are asserted for the appropriate length of time and are de-asserted in the correct order. It is also up to software to not assert a module reset signal that would prevent software from de-asserting the module reset signal. For example, software should not assert the module reset to the CPU executing the software. Software writes a bit to 1 to assert the module reset signal and to 0 to de-assert the module reset signal. All fields except CPU1 are only reset by a cold reset. The CPU1 field is reset by a cold reset. The CPU1 field is also reset by a warm reset if not masked by the corresponding MPUWARMMASK field.

mpumodrst Fields

Bit	Name	Description	Access	Reset
4	l2	Resets L2 cache controller	RW	0x0
3	scuper	Resets SCU and peripherals. Peripherals consist of the interrupt controller, global timer, both per-CPU private timers, and both per-CPU watchdogs (except for the Watchdog Reset Status registers).	RW	0x0
2	wds	Resets both per-CPU Watchdog Reset Status registers in MPU.	RW	0x0
1	cpu1	Resets Cortex-A9 CPU1 in MPU. It is reset to 1 on a cold or warm reset. This holds CPU1 in reset until software is ready to release CPU1 from reset by writing 0 to this field. On single-core devices, writes to this field are ignored.On dual-core devices, writes to this field trigger the same sequence as writes to the CPU0 field (except the sequence is performed on CPU1).	RW	0x1

Bit	Name	Description	Access	Reset
0	cpu0	Resets Cortex-A9 CPU0 in MPU. Whe software changes this field from 0 to 1, ittriggers the following sequence: 1. CPU0 reset is asserted. cpu0 clkoff is de-asserted 2. after 32 osc1_clk cycles, cpu0 clkoff is asserted. When software changes this field from 1 to 0, it triggers the following sequence: 1.CPU0 reset is de-asserted. 2. after 32 cycles, cpu0 clkoff is de-asserted. Software needs to wait for at least 64 osc1_clk cycles between each change of this field to keep the proper reset/clkoff sequence.	RW	0x0

permodrst

The PERMODRST register is used by software to trigger module resets (individual module reset signals). Software explicitly asserts and de-asserts module reset signals by writing bits in the appropriate *MODRST register. It is up to software to ensure module reset signals are asserted for the appropriate length of time and are de-asserted in the correct order. It is also up to software to not assert a module reset signal that would prevent software from de-asserting the module reset signal. For example, software should not assert the module reset to the CPU executing the software. Software writes a bit to 1 to assert the module reset signal and to 0 to de-assert the module reset signal. All fields are reset by a cold reset.All fields are also reset by a warm reset if not masked by the corresponding PERWARMMASK field. The reset value of all fields is 1. This holds the corresponding module in reset until software is ready to release the module from reset by writing 0 to its field.

per2modrst

The PER2MODRST register is used by software to trigger module resets (individual module reset signals). Software explicitly asserts and de-asserts module reset signals by writing bits in the appropriate *MODRST register. It is up to software to ensure module reset signals are asserted for the appropriate length of time and are de-asserted in the correct order. It is also up to software to not assert a module reset signal that would prevent software from de-asserting the module reset signal. For example, software should not assert the module reset to the CPU executing the software. Software writes a bit to 1 to assert the module reset signal and to 0 to de-assert the module reset signal. All fields are reset by a cold reset.All fields are also reset by a warm reset if not masked by the corresponding PERWARMMASK field. The reset value of all fields is 1. This holds the corresponding module in reset until software is ready to release the module from reset by writing 0 to its field.

Date	Version	Changes
June 2014	2014.06.30	• Updated "Functional Description of Reset Manager" • Added address map and register descriptions
February 2014	2014.02.28	Updated content in sections: • Reset Sequencing • Warm Reset Assertion Sequence
December 2013	2013.12.30	Minor formatting issues
November 2012	1.2	• Added cold and warm reset timing diagrams. • Minor updates.
May 2012	1.1	Added reset controller, functional description, and address map and register definitions sections.
January 2012	1.0	Initial release.

FPGA Manager 4

2014.06.30

cv_54013 Subscribe Send Feedback

The FPGA manager in the hard processor system (HPS) manages and monitors the FPGA portion of the system on a chip (SoC) device. The FPGA manager can configure the FPGA fabric from the HPS, monitor the state of the FPGA, and drive or sample signals to or from the FPGA fabric.

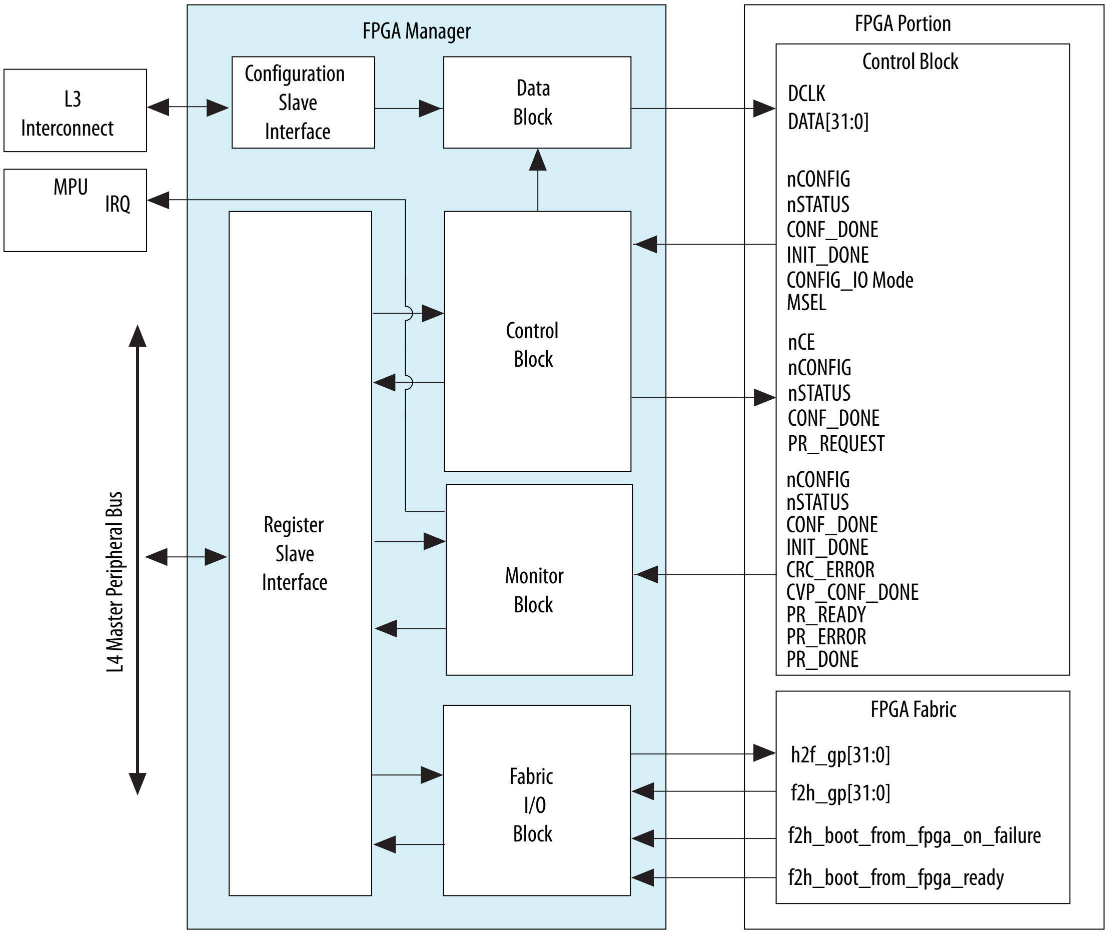
Features of the FPGA Manager

The FPGA manager provides the following functionality and features:

- Full configuration and partial reconfiguration of the FPGA portion of the SoC device
- Drives 32 general-purpose output signals to the FPGA fabric
- Receives 32 general-purpose input signals from the FPGA fabric
- Receives two boot handshaking input signals from the FPGA fabric (used when the HPS boots from the FPGA)
- Monitors the FPGA configuration and power status
- Generates interrupts based on the FPGA status changes
- Can reset the FPGA

FPGA Manager Block Diagram and System Integration

Figure 4-1: FPGA Manager Block Diagram



The register slave interface connects to the level 4 (L4) master peripheral bus for control and status register (CSR) access. The configuration slave interface connects to the level 3 (L3) interconnect for the microprocessor unit (MPU) subsystem or other masters to write the FPGA configuration image to the FPGA control block (CB) when configuring the FPGA portion of the SoC device.

The general-purpose I/O and boot handshaking input interfaces connect to the FPGA fabric. The FPGA manager also connects to the FPGA CB signals to monitor and control the FPGA portion of the device.

The FPGA manager consists of the following blocks:

- Configuration slave interface—accepts and transfers the configuration image to the data interface.
- Register slave interface—accesses the CSRs in the FPGA manager.
- Data—accepts the FPGA configuration image from the configuration slave interface and sends it to the FPGA CB.
- Control—controls the FPGA CB.
- Monitor—monitors the configuration signals in the FPGA CB and sends interrupts to the MPU subsystem.
- Fabric I/O—reads and writes signals from or to the FPGA fabric.

Functional Description of the FPGA Manager

FPGA Manager Building Blocks

The FPGA manager has the two blocks - fabric I/O and monitor. These blocks are to monitor the signals coming from the FPGA portion of the device.

Related Information

FPGA Manager Address Map and Register Definitions on page 4-9

Fabric I/O

The fabric I/O block contains the following registers to allow simple low-latency communication between the HPS and the FPGA fabric:

- General-purpose input register (gpi)
- General-purpose output register (gpo)
- Boot handshaking input register (misci)

These registers are only valid when the FPGA is in user mode. Reading from these registers while the FPGA is not in user mode provides undefined data.

The 32 general-purpose input signals from the FPGA fabric are read by reading the gpi register using the register slave interface. The 32 general-purpose output signals to the FPGA fabric are generated from writes to the gpo register. For more information about FPGA manager registers, refer to "C**FPGA Manager Address Map and Register Definitions" on page 13–7.

The boot handshaking input signals from the FPGA fabric are read by reading the misci register. The f2h_boot_from_fpga_ready signal indicates to the boot ROM when logic in the FPGA fabric is ready to accept configuration interface requests from the HPS-to-FPGA bridge when the boot ROM is booting from the FPGA. The f2h_boot_from_fpga_on_failure signal serves as a fallback in the event that the boot ROM code fails to boot from the primary boot flash device. In this case, the boot ROM code checks these two handshaking signals to determine if it should use the boot code hosted in the FPGA memory as the next stage in the boot process.

There is no interrupt support for this block.

Monitor

The monitor block is an instance of the Synopsys DesignWareGPIO IP (DW_apb_gpio), which is a separate instance of the IP that comprises the three HPS GPIO interfaces. The monitor block connects to the configuration signals in the FPGA. This block monitors key signals related to FPGA configuration such as INIT_DON E, CRC_ERROR, and PR_DONE. Software configures the monitor block through the register slave interface, and can either poll FPGA signals or be interrupted. The **mon** address map within the FPGA manager register address map contains the monitor registers. For more information about FPGA manager registers, refer to **Figure 4-1**

You can program the FPGA manager to treat any of the monitor signals as interrupt sources. Independent of the interrupt source type, the monitor block always drives an active-high level interrupt to the MPU. Each interrupt source can be of the following types:

- Active-high level
- Active-low level
- Rising edge
- Falling edge

FPGA Configuration

You can configure the FPGA using an external device or through the HPS. This section covers configuring the FPGA through the HPS.

For information about configuring the FPGA using an external device, refer to the *Configuration, Design Security, and Remote System Upgrades* chapter in the Cyclone V Device Handbook, Volume 1.

The FPGA CB uses the FPGA mode select (`MSEL`) pins to determine which configuration scheme to use. The `MSEL` pins must be tied to the appropriate values for the configuration scheme. The table below lists supported `MSEL` values when the FPGA is configured by the HPS.

HPS software sets the clock-to-data ratio field (`cdratio`) and configuration data width bit (`cfgwdth`) in the control register (`ctrl`) to match the `MSEL` pins. The `cdratio` field and `cfgwdth` bit must be set before the start of configuration.

The FPGA manager connects to the configuration logic in the FPGA portion of the device using a mode similar to how external logic (for example, MAX II or an intelligent host) configures the FPGA in fast passive parallel (FPP) mode. FPGA configuration through the HPS supports all the capabilities of FPP mode, including the following items:

- FPGA configuration
- Partial FPGA reconfiguration
- FPGA I/O configuration, followed by PCI Express® (PCIe®) configuration of the remainder of FPGA
- External single event upset (SEU) scrubbing
- Decompression
- Advanced Encryption Standard (AES) encryption
- FPGA `DCLK` clock used for initialization phase clock

Note: The FPGA manager supports a data width of 32 or 16 bits. When configuring the FPGA fabric from the HPS, Altera recommends that you always set the data width to 32 bits. For partial reconfiguration, the 16-bit data width is the only option.

The following table lists the supported configuration schemes and their respective MSEL and control register settings when the HPS configures the FPGA.

[4] For information about POR delay, refer to the Configuration, Design Security, and Remote System Upgrades in the Cyclone V Device Handbook, Volume 1.

[5] Other MSEL values are allowed when the FPGA is configured from a non-HPS source. For information, refer to the Configuration, DesignSecurity, and Remote System Upgrades in the Cyclone V Device Handbook, Volume 1.

[6] You can select to enable or disable this feature.

[7] You can select to enable or disable this feature.

Table 4-1: Configuration Schemes for FPGA Configuration by the HPS

Configuration Scheme	Compression Feature	Design Security Feature	POR Delay [4]	MSEL[4..0] [5]	cfgwdth	cdratio	Supports Partial Reconfiguration
FPP ×16	Disabled	AES Disabled	Fast	00000	0	1	Yes

			Standard	01101	1	4	No
	Enabled	Optional [7]	Fast	01010	1	8	No
			Standard	01110	1	8	No

Configuring the FPGA portion of the SoC device comprises the following phases:

1. Power up phase
2. Reset phase
3. Configuration phase
4. Initialization phase
5. User mode

Related Information

http://www.altera.com/literature/hb/cyclone-v/cv_52007.pdf
For more information about configuring the FPGA through the HPS, refer to the *Configuration, Design Security, and Remote System Upgrade* appendix in the Cyclone V Device Handbook, Volume 1.

Power Up Phase

In this phase, the VCC is ramping up and has yet to reach normal levels. This phase completes when the on-chip voltage detector determines that the VCC has reached normal levels.

Reset Phase

The FPGA manager resets the FPGA portion of the SoC device when the FPGA configuration signal (`nCONFIG`) is driven low. The HPS configures the FPGA by writing a 1 to the `nconfigpull` bit of the `ctrl` register. This action causes the FPGA portion of the device to reset and perform the following actions:

1. Clear the FPGA configuration RAM bits
2. Tri-state all FPGA user I/O pins
3. Pull the `nSTATUS` and `CONF_DONE` pins low
4. Use the FPGA CB to read the values of the `MSEL` pins to determine the configuration scheme

The `nconfigpull` bit of the `ctrl` register needs to be set to 0 when the FPGA has successfully entered the reset phase. Setting the bit releases the FPGA from the reset phase and transitions to the configuration phase.

Note: You must set the `cdratio` and `cfgwdth` bits of the `ctrl` register appropriately before the FPGA enters the reset phase.

Configuration Phase

To configure the FPGA using the HPS, software sets the `axicfgen` bit of the `ctrl` register to 1. Software then sends configuration data to the FPGA by writing data to the write data register (`data`) in the FPGA manager module configuration data address map. Software polls the `CONF_DONE` pin by reading the `gpio_instatus` register to determine if the FPGA configuration is successful. When configuration is successful, software sets the `axicfgen` bit of the `ctrl` register to 0. The FPGA user I/O pins are still tri-stated in this phase.

After successfully completing the configuration phase, the FPGA transitions to the initialization phase. To delay configuring the FPGA, set the `confdonepull` bit of the `ctrl` register to 1.

Related Information

Booting and Configuration Introduction on page 30-1
For more information about configuring the FPGA through the HPS, refer to the *Booting and Configuration* appendix.

Initialization Phase

In this phase, the FPGA prepares to enter user mode. The internal oscillator in the FPGA portion of the device is the default clock source for the initialization phase. Alternatively, the configuration image can specify the `CLKUSR` or the `DCLK` pins as the clock source. The alternate clock source controls when the FPGA enters user mode.

If `DCLK` is selected as the clock source, software uses the `DCLK` count (`dclkcnt`) register to drive `DCLK` pulses to the FPGA. Writing to the `cnt` field of the `dclkcnt` register triggers the FPGA manager to generate the specified number of `DCLK` pulses. When all of the `DCLK` pulses have been sent, the `dcntdone` bit of the `DCLK` status (`dclkstat`) register is set to 1. Software polls the `dcntdone` bit to know when all of the `DCLK` pulses have been sent.

Note: Before another write to the `dclkcnt` register, software needs to write a value of 1 to the `dcntdone` bit to clear the done state.

The FPGA user I/O pins are still tri-stated in this phase. When the initialization phase completes, the FPGA releases the optional `INIT_DONE` pin and an external resistor pulls the pin high.

User Mode

The FPGA enters the user mode after exiting the initialization phase. The FPGA user I/O pins are no longer tri-stated in this phase and the configured soft logic in the FPGA becomes active.

The FPGA remains in user mode until the `nCONFIG` pin is driven low. If the `nCONFIG` pin is driven low, the FPGA reenters the reset phase. The internal oscillator is disabled in user mode, but is enabled as soon as the `nCONFIG` pin is driven low.

  For more information about configuring the FPGA through the HPS, refer to the *Booting and Configuration* appendix.

FPGA Status

Configuration signals from the FPGA CSS such as INIT_DONE, CRC_ERROR and PR_DONE are monitored by the FPGA Manager. Software configures the monitor block through the register slave interface, and can either poll FPGA signals or be interrupted. Monitored signals can be read through an unmasked status register as well as a masked status register. Each of the monitored signals can generate an interrupt to the MPU Global Interrupt Controller. Each interrupt source can be enabled and the polarity of the signals generating the interrupt can also be selected through registers in the FPGA Manager.

Error Message Extraction

Cyclic redundancy check (CRC) errors from the FPGA fabric are monitored by the FPGA Manager. Upon assertion of a CRC error signal from the FPGA, the FPGA Manager extracts information about the error including:

- Error syndrome
- Error location
- Error type

A CRC error interrupt from the FPGA Manager can be enabled via software. Software can then extract the CRC error information from the EMR data registers. The number of valid error information bits in the EMR data registers depends on the specific FPGA device.

Data AES Decryption

The Configuration Data Interface can also be used to transmit data from the HPS to the CSS Advanced Encryption Standard (AES) decryption engine. Software should sample the status registers in FPGA manager before switching modes between FPGA configuration and AES decryption. The FPGA manager does not do anything specific to handle a situation where software starts an AES decryption while in the middle of an FPGA configuration initiated by HPS, and the end result in this case is undefined.

JTAG Hosting

The FPGA Manager has the capability to host the JTAG interface to the CSS. In this mode the FPGA Manger will take over the FPGA JTAG interface to CSS via mux overrides thus bypassing the JTAG device pins. This interface is disabled by default. When JTAG hosting is turned on the FPGA Manager also provides a JTAG interface to the FPGA core which could be used by soft logic in the FPGA.

JTAG hosting provides the capability for:

- Secure remote debug
- Secure remote key insertion
- Remote FPGA configuration

Boot Handshake

There are two input signals from the FPGA to control HPS boot from the FPGA. Both are synchronized within the FPGA Manager. Boot software will read these signals before accessing a boot image in the FPGA. The following table describes the functionality of these signals.

Signal	Description
f2h_boot_from_fpga_on_failure	Indicates whether a fallback preloader image is available in an FPGA on-chip RAM at memory location 0. The fallback preloader image is to be used only if the HPS boot ROM does not find a valid preloader image in the selected flash memory device.
f2h_boot_from_fpga_ready	Indicates a preloader image is available in an FPGA on-chip RAM at memory location 0 and it is ready to be accessed.

General Purpose I/O

Thirty-two general purpose inputs and thirty-two general purpose outputs are provided to the FPGA and are controlled through registers in the FPGA Manager.

No interrupts are generated through the input pins. All inputs are synchronized within the FPGA Manager. Output signals should be synchronized in the FPGA.

Clock

The FPGA manager has two clock input signals which are asynchronous to each other. The clock manager generates these two clocks:

- cfg_clk—the configuration slave interface clock input and also the DCLK output reference for FPGA configuration. Enable this clock in the clock manager only when configuration is active or when the configuration slave interface needs to respond to master requests.
- l4_mp_clk—the register slave interface clock.

Related Information

Clock Manager on page 2-1

Reset

The FPGA manager has one reset signal. The reset manager drives this signal to FPGA manager on a cold or warm reset. All distributed reset signals in the FPGA manager are asserted asynchronously at the same time and de-asserted synchronously to their associated clocks.

data

Used to send configuration image to FPGA. The DATA register accepts 4 bytes of the configuration image on each write. The configuration image byte-stream is converted into a 4-byte word with little-endian ordering. If the configuration image is not an integer multiple of 4 bytes, software should pad the configuration image with extra zero bytes to make it an integer multiple of 4 bytes. The FPGA Manager converts the DATA to 16 bits wide when writing CB.DATA for partial reconfiguration. The FPGA Manager waits to transmit the data to the CB until the FPGA is able to receive it. For a full configuration, the FPGA Manager waits until the FPGA exits the Reset Phase and enters the Configuration Phase. For a partial reconfiguration, the FPGA Manager waits until the CB.PR_READY signal indicates that the FPGA is ready.

stat

Provides status fields for software for the FPGA Manager. The Mode field tells software what configuration phase the FPGA currently is in. For regular configuration through the PINs or through the HPS, these states map directly to customer configuration documentation. For Configuration Via PCI Express (CVP), the IOCSR configuration is done through the PINS or through HPS. Then the complete configuration is done through the PCI Express Bus. When CVP is being done, InitPhase indicates only IOCSR configuration has completed. CVP_CONF_DONE is available in the CB Monitor for observation by software. The MSEL field provides a read only register for software to read the MSEL value driven from the external pins.

Bit	Name	Description	Access	Reset
2:0	`mode`	Reports FPGA state **Value** **Description** 0x0 FPGA Powered Off 0x1 FPGA in Reset Phase 0x2 FPGA in Configuration Phase 0x3 FPGA in Initialization Phase. In CVP configuration, this state indicates IO configuration has completed. 0x4 FPGA in User Mode 0x5 FPGA state has not yet been determined. This only occurs briefly after reset.	`RW`	`0x5`

ctrl

Allows HPS to control FPGA configuration. The NCONFIGPULL, NSTATUSPULL, and CONFDONEPULL fields drive signals to the FPGA Control Block that are logically ORed into their respective pins. These signals are always driven independent of the value of EN. The polarity of the NCONFIGPULL, NSTATUSPULL, and CONFDONEPULL fields is inverted relative to their associated pins. The MSEL (external pins), CDRATIO and CFGWDTH signals determine the mode of operation for Normal Configuration. For Partial Reconfiguration, CDRATIO is used to set the appropriate clock to data ratio, and CFGWDTH should always be set to 16-bit Passive Parallel. AXICFGEN is used to enable transfer of configuration data by enabling or disabling DCLK during data transfers.

ctrl Fields

Bit	Name	Description	Access	Reset
9	cfgwdth	This field determines the Configuration Passive Parallel data bus width when HPS configures the FPGA. Only 32-bit Passive Parallel or 16-bit Passive Parallel are supported. When HPS does Normal Configuration, configuration should use 32-bit Passive Parallel Mode. The external pins MSEL must be set appropriately for the configuration selected. For Partial Reconfiguration, 16-bit Passive Parallel must be used. **Value** — **Description** 0x0 — 16-bit Passive Parallel 0x1 — 32-bit Passive Parallel	RW	0x1
8	axicfgen	There are strict SW initialization steps for configuration, partial configuration and error cases. When SW is sending configuration files, this bit must be set before the file is transferred on the AXI bus. This bit enables the DCLK during the AXI configuration data transfers. Note, the AXI and configuration datapaths remain active irregardless of the state of this bit. Simply, if the AXI slave is enabled, the DCLK to the CB will be active. If disabled, the DCLK to the CB will not be active. So AXI transfers destined to the FPGA Manager when AXIEN is 0, will complete normally from the HPS perspective. This field only affects the FPGA if CTRL.EN is 1. **Value** — **Description** 0x0 — Incoming AXI data transfers will be ignored. DCLK will not toggle during data transfer. 0x1 — AXI data transfer to CB is active. DCLK will toggle during data transfer.	RW	0x0

Bit	Name	Description	Access	Reset
7:6	`cdratio`	This field controls the Clock to Data Ratio (CDRATIO) for Normal Configuration and Partial Reconfiguration data transfer from the AXI Slave to the FPGA. For Normal Configuration, the value in this field must be set to be consistent to the implied CD ratio of the MSEL setting. For Partial Reconfiguration, the value in this field must be set to the same clock to data ratio in the options bits in the Normal Configuration file. **Value** / **Description** 0x0 CDRATIO of 1 0x1 CDRATIO of 2 0x2 CDRATIO of 4 0x3 CDRATIO of 8	`RW`	`0x0`
5	`prreq`	This field is used to assert PR_REQUEST to request partial reconfiguration while the FPGA is in User Mode. This field only affects the FPGA if CTRL.EN is 1. **Value** / **Description** 0x0 De-assert PR_REQUEST (driven to 0). 0x1 Assert PR_REQUEST (driven to 1).	`RW`	`0x0`
4	`confdonepull`	Pulls down CONF_DONE input to the CB **Value** / **Description** 0x0 Don't pull-down CONF_DONE input to the CB. 0x1 Pull-down CONF_DONE input to the CB.	`RW`	`0x0`
3	`nstatuspull`	Pulls down nSTATUS input to the CB **Value** / **Description** 0x0 Don't pull-down nSTATUS input to the CB. 0x1 Pull-down nSTATUS input to the CB.	`RW`	`0x0`

Bit	Name	Description	Access	Reset
2	`nconfigpull`	The nCONFIG input is used to put the FPGA into its reset phase. If the FPGA was configured, its operation stops and it will have to be configured again to start operation. **Value** **Description** 0x0 Don't pull-down nCONFIG input to the CB. 0x1 Pull-down nCONFIG input to the CB. This puts the FPGA in reset phase and restarts configuration.	RW	0x0
1	`nce`	This field drives the active-low Chip Enable (nCE) signal to the CB. It should be set to 0 (configuration enabled) before CTRL.EN is set. This field only effects the FPGA if CTRL.EN is 1. **Value** **Description** 0x0 Configuration is enabled. The nCE to the CB is driven to 0. 0x1 Configuration is disabled. The nCE to the CB is driven to 1.	RW	0x0
0	`en`	Controls whether the FPGA configuration pins or HPS FPGA Manager drive configuration inputs to the CB. **Value** **Description** 0x0 FPGA configuration pins drive configuration inputs to the CB. Used when FPGA is configured by means other than the HPS. 0x1 FPGA Manager drives configuration inputs to the CB. Used when HPS configures the FPGA.	RW	0x0

dclkcnt

Used to give software control in enabling DCLK at any time. SW will need control of the DCLK in specific configuration and partial reconfiguration initialization steps to send spurious DCLKs required by the CB. SW takes ownership for DCLK during normal configuration, partial reconfiguration, error scenerio handshakes including SEU CRC error during partial reconfiguration, SW early abort of partial reconfiguration, and initializatin phase DCLK driving. During initialization phase, a configuration image loaded into the FPGA can request that DCLK be used as the initialization phase clock instead of the default internal oscillator or optionally the CLKUSR pin. In the case that DCLK is requested, the DCLKCNT register is used by software to control DCLK during the initialization phase. Software should poll the DCLKSTAT.DCNTDONE write one to clear register to be set when the correct number of

DCLKs have completed. Software should clear DCLKSTAT.DCNTDONE before writing to the DCLKCNT register again. This field only affects the FPGA if CTRL.EN is 1.

dclkcnt Fields

Bit	Name	Description	Access	Reset
31:0	`cnt`	Controls DCLK counter. Software writes a non-zero value into CNT and the FPGA Manager generates the specified number of DCLK pulses and decrements COUNT. This register will read back the original value written by software. Software can write CNT at any time.	`RW`	`0x0`

dclkstat

This write one to clear register indicates that the DCLKCNT has counted down to zero. The DCLKCNT is used by software to drive spurious DCLKs to the FPGA. Software will poll this bit after writing DCLKCNT to know when all of the DCLKs have been sent.

Configuration Monitor (MON) Registers Register Descriptions

The Configuration Monitor allows software to poll or be interrupted by changes in the FPGA state. The Configuration Monitor is an instantiation of a Synopsys GPIO.

Only registers relevant to the MON operation are shown. The GPIO inputs are connected to the following signals:

- nSTATUS - Driven to 0 by the FPGA in this device if the FPGA is in Reset Phase or if the FPGA detected an error during the Configuration Phase.
- CONF_DONE - Driven to 0 by the FPGA in this device during the Reset Phase and driven to 1 when the FPGA Configuration Phase is done.
- INIT_DONE - Driven to 0 by the FPGA in this device during the Configuration Phase and driven to 1 when the FPGA Initialization Phase is done.
- CRC_ERROR - CRC error indicator. A CRC_ERROR value of 1 indicates that the FPGA detected a CRC error while in User Mode.
- CVP_CONF_DONE - Configuration via PCIe done indicator. A CVP_CONF_DONE value of 1 indicates that CVP is done.
- PR_READY - Partial reconfiguration ready indicator. A PR_READY value of 1 indicates that the FPGA is ready to receive partial reconfiguration or external scrubbing data.
- PR_ERROR - Partial reconfiguration error indicator. A PR_ERROR value of 1 indicates that the FPGA detected an error during partial reconfiguration or external scrubbing.
- PR_DONE - Partial reconfiguration done indicator. A PR_DONE value of 1 indicates partial reconfiguration or external scrubbing is done.
- nCONFIG Pin - Value of the nCONFIG pin. This can be pulled-down by the FPGA in this device or logic external to this device connected to the nCONFIG pin. See the description of the nCONFIG field in this register to understand when the FPGA in this device pulls-down the nCONFIG pin. Logic external to this device pulls-down the nCONFIG pin to put the FPGA into the Reset Phase.

- nSTATUS Pin - Value of the nSTATUS pin. This can be pulled-down by the FPGA in this device or logic external to this device connected to the nSTATUS pin. See the description of the nSTATUS field in this register to understand when the FPGA in this device pulls-down the nSTATUS pin. Logic external to this device pulls-down the nSTATUS pin during Configuration Phase or Initialization Phase if it detected an error.
- CONF_DONE Pin - Value of the CONF_DONE pin. This can be pulled-down by the FPGA in this device or logic external to this device connected to the CONF_DONE pin. See the description of the CONF_DONE field in this register to understand when the FPGA in this device pulls-down the CONF_DONE pin. See FPGA documentation to determine how logic external to this device drives CONF_DONE.
- FPGA_POWER_ON - FPGA powered on indicator
  - 0 = FPGA portion of device is powered off.
  - 1 = FPGA portion of device is powered on.

Offset: `0x800`

gpio_inten on page 4-23
Allows each bit of Port A to be configured to generate an interrupt or not.

gpio_intmask on page 4-25
This register has 12 individual interrupt masks for the MON. Controls whether an interrupt on Port A can create an interrupt for the interrupt controller by not masking it. By default, all interrupts bits are unmasked. Whenever a 1 is written to a bit in this register, it masks the interrupt generation capability for this signal; otherwise interrupts are allowed through. The unmasked status can be read as well as the resultant status after masking.

gpio_inttype_level on page 4-28
The interrupt level register defines the type of interrupt (edge or level) for each GPIO input.

gpio_int_polarity on page 4-31
Controls the polarity of interrupts that can occur on each GPIO input.

gpio_intstatus on page 4-34
Reports on interrupt status for each GPIO input. The interrupt status includes the effects of masking.

gpio_raw_intstatus on page 4-36
Reports on raw interrupt status for each GPIO input. The raw interrupt status excludes the effects of masking.

gpio_porta_eoi on page 4-39
This register is written by software to clear edge interrupts generated by each individual GPIO input. This register always reads back as zero.

gpio_ext_porta on page 4-41
Reading this register reads the values of the GPIO inputs.

gpio_ls_sync on page 4-42
The Synchronization level register is used to synchronize inputs to the l4_mp_clk. All MON interrupts are already synchronized before the GPIO instance so it is not necessary to setup this register to enable synchronization.

gpio_ver_id_code on page 4-43
GPIO Component Version

gpio_config_reg2 on page 4-44
Specifies the bit width of port A.

gpio_config_reg1 on page 4-45
Reports settings of various GPIO configuration parameters

gpio_inten

Allows each bit of Port A to be configured to generate an interrupt or not.

4	`ccd`	Controls whether an interrupt for CVP_CONF_DONE can generate an interrupt to the interrupt controller by not masking it. The unmasked status can be read as well as the resultant status after masking. **Value** **Description** 0x0 Unmask Interrupt 0x1 Mask Interrupt	`RW`	`0x0`

Bit	Name	Description	Access	Reset
3	`crc`	Controls whether an interrupt for CRC_ERROR can generate an interrupt to the interrupt controller by not masking it. The unmasked status can be read as well as the resultant status after masking. **Value** — **Description** 0x0 — Unmask Interrupt 0x1 — Mask Interrupt	`RW`	`0x0`
2	`id`	Controls whether an interrupt for INIT_DONE can generate an interrupt to the interrupt controller by not masking it. The unmasked status can be read as well as the resultant status after masking. **Value** — **Description** 0x0 — Unmask Interrupt 0x1 — Mask Interrupt	`RW`	`0x0`
1	`cd`	Controls whether an interrupt for CONF_DONE can generate an interrupt to the interrupt controller by not masking it. The unmasked status can be read as well as the resultant status after masking. **Value** — **Description** 0x0 — Unmask Interrupt 0x1 — Mask Interrupt	`RW`	`0x0`
0	`ns`	Controls whether an interrupt for nSTATUS can generate an interrupt to the interrupt controller by not masking it. The unmasked status can be read as well as the resultant status after masking. **Value** — **Description** 0x0 — Unmask Interrupt 0x1 — Mask Interrupt	`RW`	`0x0`

gpio_inttype_level

The interrupt level register defines the type of interrupt (edge or level) for each GPIO input.

Module Instance	Base Address	Register Address
`fpgamgrregs`	`0xFF706000`	`0xFF706838`

Offset: `0x838`

Access: RW

gpio_config_reg1 Fields

Bit	Name	Description	Access	Reset
20:16	encoded_id_width	This value is fixed at 32 bits. **Value** **Description** 0x1f Width of ID Field	RO	0x1F
15	gpio_id	Provides an ID code value **Value** **Description** 0x0 GPIO ID Code Register Excluded	RO	0x0

Bit	Name	Description	Access	Reset
14	`add_encoded_params`	Fixed to allow the indentification of the Designware IP component. **Value** — **Description** 0x1 — Enable IP indentification	RO	0x1
13	`debounce`	The value of this field is fixed to not allow debouncing of the Port A signals. **Value** — **Description** 0x0 — Debounce is Disabled	RO	0x0
12	`porta_intr`	The value of this field is fixed to allow interrupts on Port A. **Value** — **Description** 0x1 — Port A Interrupts Enabled	RO	0x1
8	`hw_porta`	The value is fixed to enable Port A configuration to be controlled by software only. **Value** — **Description** 0x0 — Software Configuration Control Enabled	RO	0x0
7	`portd_single_ctl`	Indicates the mode of operation of Port D to be software controlled only. Ignored because there is no Port D in the GPIO. **Value** — **Description** 0x1 — Software Enabled Individual Port Control	RO	0x1
6	`portc_single_ctl`	Indicates the mode of operation of Port C to be software controlled only. Ignored because there is no Port C in the GPIO. **Value** — **Description** 0x1 — Software Enabled Individual Port Control	RO	0x1

Bit	Name	Description	Access	Reset
5	`portb_single_ctl`	Indicates the mode of operation of Port B to be software controlled only. Ignored because there is no Port B in the GPIO. **Value** **Description** 0x1 Software Enabled Individual Port Control	RO	0x1
4	`porta_single_ctl`	Indicates the mode of operation of Port A to be software controlled only. **Value** **Description** 0x1 Software Enabled Individual Port Control	RO	0x1
3:2	`num_ports`	The value of this register is fixed at one port (Port A). **Value** **Description** 0x0 Number of GPIO Ports = 1	RO	0x0
1:0	`apb_data_width`	Fixed to support an APB data bus width of 32-bits. **Value** **Description** 0x2 APB Data Width = 32-bits	RO	0x2

Document Revision History

Table 4-2: Document Revision History

Date	Version	Changes
June 2014	2014.06.30	Added address maps and register definitions
February 2014	2014.02.28	Maintenance release
December 2013	2013.12.30	Minor updates.
November 2012	1.3	Minor updates.
June 2012	1.2	Updated the FPGA configuration section.

Date	Version	Changes
May 2012	1.1	• Updated the configuration schemes table. • Updated the FPGA configuration section. • Added address map and register definitions section.
January 2012	1.0	Initial release.

System Manager 5

2014.06.30

cv_54014 Subscribe Send Feedback

The system manager in the hard processor system (HPS) contains memory-mapped control and status registers (CSRs) and logic to control system level functions as well as other modules in the HPS.

The system manager connects to the following modules in the HPS:

- Direct memory access (DMA) controller
- Ethernet media access controllers (EMAC0 and EMAC1)
- Microprocessor unit (MPU) subsystem
- NAND flash controller
- Secure Digital/MultiMediaCard (SD/MMC) controller
- Quad serial peripheral interface (SPI) flash controller
- USB 2.0 On-The-Go (OTG) controllers (USB0 and USB1)
- Watchdog timers

Features of the System Manager

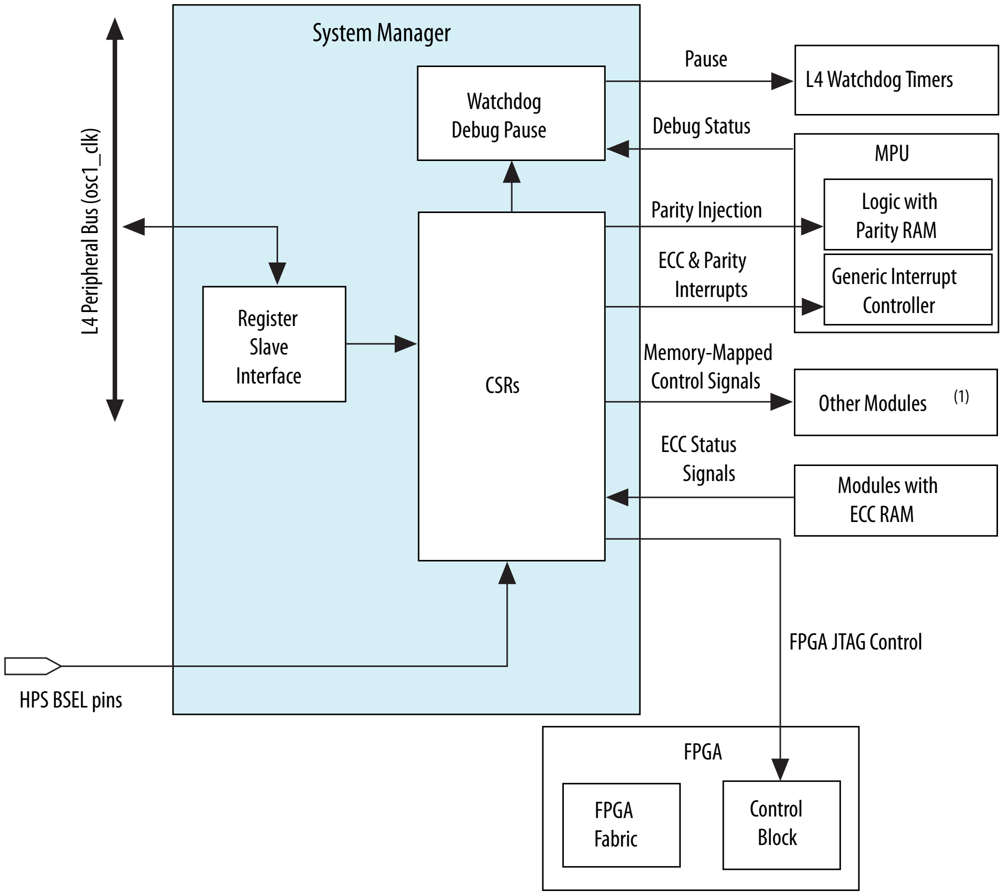
Software accesses the CSRs in the system manager to control and monitor various functions in other HPS modules that require external control signals. The system manager connects to these modules to perform the following functions:

- Sends pause signals to pause the watchdog timers when the processors in the MPU subsystem are in debug mode.
- Selects the EMAC level 3 (L3) master signal options .
- Freezes the I/O pins after the HPS comes out of cold reset and during serial configuration.
- Selects the SD/MMC controller clock options and L3 master signal options.
- Selects the NAND flash controller bootstrap options and L3 master signal options.
- Selects USB controller L3 master signal options.
- Provides control over the DMA security settings when the HPS exits from reset.
- Provides boot source and clock source information that can be read during the boot process.
- Provides the capability to enable/disable an interface of signals to the FPGA.
- Routes parity failure interrupts from the L1 caches to the Global Interrupt Controller.
- Sends error correction code (ECC) enable signals to all HPS modules with ECC protected RAM.
- Provides the capability to inject errors during testing in the MPU L2 ECC-protected RAM.

System Manager Block Diagram and System Integration

The system manager connects to the level 4 bus through a slave interface. The CSRs connect to signals in the FPGA and also to other HPS modules.

Figure 5-1: System Manager Block Diagram



The system manager consists of the following blocks:

- CSRs—Provide memory-mapped access to control signals and status for the following HPS modules:
  - EMACs
  - Debug core
  - SD/MMC controller
  - NAND controller
  - USB controllers
  - DMA controller
  - L3 Interconnect
  - ECC and parity interrupt routing to the MPU
  - Status information received from other HPS modules
- Register slave interface—provides connected masters access to the CSRs in the system manager.
- Watchdog debug pause—accepts the debug mode status from the MPU subsystem and pauses the L4 watchdog timers.

Functional Description of the System Manager

The system manager serves the following purposes:

- Provides software access to boot configuration and system information
- Provides software access to control and status signals in other HPS modules
- Provides combined ECC status and interrupt from other HPS modules with ECC-protected RAM
- Enables and disables HPS peripheral interfaces to the FPGA
- Provides eight registers that software can use to pass information between boot stages

Boot Configuration and System Information

The system manager provides boot configuration information through the `bootinfo` register. The following information is available to the Boot ROM software:

- Sampled value of the HPS boot select (`BSEL`) pins

The boot configuration information comes from the HPS `BSEL` pins. The `BSEL` signal informs Boot ROM software which flash device CPU0 booted from.

Related Information

Booting and Configuration

For boot and clock source values, refer to the *Booting and Configuration* appendix in the *Cyclone V Device Handbook, Volume 3*.

Additional Module Control

Each module in the HPS has its own CSRs, providing access to the internal state of the module. The system manager CSRs provide access to additional module state information, enabling additional control and monitoring. To fully control each module, you must manipulate both the module's own CSRs, and CSRs in the system manager. This section describes system manager CSR usage for each module.

DMA Controller

The security state of the DMA controller is controlled by the manager thread security `mgr_ns` and interrupt security (`irq_ns`) bits of the `dma` register.

Note: Register bits should be accessed by drivers or user application software only when the DMA master interface is guaranteed to be inactive.

Related Information

DMA Controller on page 16-1

NAND Flash Controller

The bootstrap control register (`nand_bootstrap`) modifies the default behavior of the NAND flash controller after reset. The NAND flash controller samples the register bits when it comes out of reset.

The following `bootstrap` register bits control configuration of the NAND flash controller:

- Bootstrap inhibit initialization bit (`noinit`)—inhibits the NAND flash controller from initializing when coming out of reset, and allows software to program all registers pertaining to device parameters such as page size and width.
- Bootstrap 512 byte device bit (`page512`)—informs the NAND flash controller that a NAND flash device of 512 byte page size is connected to the system.
- Bootstrap inhibit load block 0 page 0 bit (`noloadb0p0`)—inhibits the NAND flash controller from loading page 0 of block 0 of the NAND flash device as part of the initialization procedure.
- Bootstrap two row address cycles bit (`tworowaddr`)—informs the NAND flash controller that only two ROW address cycles are required instead of the default three row address cycles.

Registers in the system manager control the L3 master `ARCACHE` and `AWCACHE` signals. Set the NAND arcache (`arcache`) and NAND awcache (`awcache`) bits of the NAND L3 master AxCACHE register (`l3master`) to control these selections. These bits define the cache attributes for the master transactions of the DMA engine in the NAND controller.

Note: Register bits should be accessed only when the master interface is guaranteed to be in an inactive state.

Related Information

NAND Flash Controller on page 13-1

CAN Controller

The switching between the CAN controller and FPGA interfaces is controlled by the system manager. The DMA channels can be dedicated to the FPGA or to one of the four CAN interfaces.

Table 5-1: Peripheral Request Interface mapping

DMA Channel	Peripheral	CAN Controller
channel 0	FPGA 4	CAN0 interface 1
channel 1	FPGA 5	CAN0 interface 2
channel 2	FPGA 6	CAN1 interface 1
channel 3	FPGA 7	CAN1 interface 2

The ctrl register controls the mux that selects whether FPGA or CAN connects to one of the DMA peripherals request interfaces.

Table 5-2: Control Register (ctrl)

Interface	Value
FPGA	0x0
CAN	0x1

Related Information

  For more information on the System Manger's registers, refer to the *Cyclone V SoC HPS Address Map and Register Definitions* page.

EMAC

The system manager allows software to select either emac_ptp_clk from the Clock Manager or f2s_ptp_ref_clk from the FPGA fabric as the source of the IEEE 1588 reference clock for each EMAC.

Registers in the system manager control the L3 master ARCACHE and AWCACHE signals. Set the EMAC arcache, awcache, and arprot, awprot bits to control there signals. These bits define the cache attributes for the master transactions of the DMA engine in the EMAC controllers.

The app_clk_sel bit determines the source of the clocks for the application clock. The ptp_ref_sel bit selects if the Timestamp reference is internally or externally generated. Note that EMAC0 must be set to Internal Timestamp. The phy_intf_sel bit determines if Out of Reset, GMII (or MII), RGMII or RMII would be used as the PHY interface.

Note: Register bits should be accessed only when the master interface is guaranteed to be in an inactive state.

Related Information

  For more information, refer to the Clock Manager chapter in the Cyclone V Device Handbook, Volume 3.
- **Ethernet Media Access Controller** on page 17-1

USB 2.0 OTG Controller

Registers in the system manager control the HPROT field of the USB master port of the USB 2.0 OTG Controller.

Note: Register bits should be accessed only when the master interface is guaranteed to be in an inactive state.

Related Information

USB 2.0 OTG Controller on page 18-1

SD/MMC Controller

Registers in the system manager control the HPROT field of the SD/MMC master port.

Note: Register bits should be accessed only when the master interface is guaranteed to be in an inactive state.

The system manager allows software to select the clock's phase shift for `cclk_in_drv` and `cclk_in_sample` by setting the drive clock phase shift select (`drvsel`) and sample clock phase shift select (`smplsel`) bits of the `sdmmc register`.

Related Information

SD/MMC Controller on page 14-1

Watchdog Timer

The system manager controls the watchdog timer behavior when the CPUs are in debug mode. The system manager sends a pause signal to the watchdog timers depending on the setting of the debug mode bits of the L4 watchdog debug register (`wddbg`). Each watchdog timer built into the MPU subsystem is automatically paused when its associated CPU enters debug mode.

Related Information

Watchdog Timer on page 24-1

Boot ROM Code

Registers in the system manager control whether the boot ROM code configures the pin multiplexing for boot pins after a warm reset. Set the warm-reset-configure-pin-multiplex for boot pins bit (`warmrstcfg-pinmux`) of the boot ROM code register to enable or disable this control.

Note: The boot ROM code always configures the pin multiplexing for boot pins after a cold reset.

Registers in the system manager also control whether the boot ROM code configures the I/O pins used during the boot process after a warm reset. Set the warm reset configure I/Os for boot pins bit (`warmrstcfgio`) of the `ctrl` register to enable or disable this control. By default, the boot ROM code always configures the I/O pins used by boot after a cold reset.

When CPU1 is released from reset and the boot ROM code is located at the CPU1 reset exception address (for a typical case), the boot ROM reset handler code reads the address stored in the CPU1 start address register (`cpu1startaddr`) and passes control to software at that address.

The preloader state register (`initswstate`) stores the magic number 0x49535756 written by the preloader to indicate there is a valid preloader software image in the on-chip RAM.

There can be up to four preloader images stored in flash memory. The (`initswlastld`) register contains the index of the preloader's last image that is loaded in the on-chip RAM.

The boot ROM software state register (`bootromswstate`) is a 32-bit general-purpose register reserved for the boot ROM.

The following `warmram` related registers are used to configure the warm reset from on-chip RAM feature.

Table 5-3: The warmram Registers

Register	Name	Purpose
`enable`	Enable	Controls whether the boot ROM attempts to boot from the contents of the on-chip RAM on a warm reset.

Register	Name	Purpose
`datastart`	Data start	Contains the byte offset of the warm boot CRC validation region in the on-chip RAM. The offset must be word-aligned to an integer multiple of four.
`length`	Length	Contains the length in bytes of the region in the on-chip RAM available for warm boot CRC validation.
`execution`	Execution offset	Contains the byte offset into the on-chip RAM that the boot code jumps to if the CRC validation succeeds.
`crc`	Expected CRC	Contains the expected CRC of the region in the on-chip RAM.

All the registers in the above table must be written by software prior to the warm reset occurring.

The number of wait states applied to the boot ROM's read operation is determined by the wait state bit (`waitstate`) of the `ctrl` register. After the boot process, software might require reading the code in the boot ROM. If software has changed the clock frequency of the `l3_main_clk` after reset, an additional wait state is necessary to access the boot ROM. Set the `waitstate` bit to add an additional wait state to the read access of the boot ROM. The enable safe mode warm reset update bit controls whether the wait state bit is updated during a warm reset.

L3 Interconnect

The System Manager provides remap bits to the L3 Interconnect. These bits can remap the Boot ROM and the On-chip RAM.

FPGA Interface Enables

The system manager can enable or disable interfaces between the FPGA and HPS. The interfaces must be disabled when not in use to avoid undefined behavior.

The global interface bit (`intf`) of the global disable register (`gbl`) disables all interfaces between the FPGA and HPS.

Note: Ensure that all interfaces between the FPGA and HPS are inactive before disabling them.

You can set the individual disable register (`indiv`) to disable the following interfaces between the FPGA and HPS:

- Reset request interface
- JTAG enable interface
- I/O configuration interface
- Boundary scan interface
- Debug interface
- Trace interface
- System Trace Macrocell (STM) interface
- Cross-trigger interface (CTI)
- NAND interface

- SD/MMC interface
- SPI Master interface
- EMAC interfaces

ECC and Parity Control

The system manager can enable or disable ECC for each of the following HPS modules with ECC-protected RAM:

- MPU L2 cache data RAM
- On-chip RAM
- USB 2.0 OTG controller (USB0 and USB1) RAM
- EMAC (EMAC0, EMAC1, and EMAC2) RAM
- DMA controller RAM
- CAN controller RAM
- NAND flash controller RAM
- Quad SPI flash controller RAM
- SD/MMC controller RAM
- DDR interfaces

The system manager can inject single-bit or double-bit errors into the MPU L2 ECC memories for testing purposes. Set the bits in the appropriate memory enable register to inject errors. For example, to inject a single bit EEC error, set the `injs` bit of the mpu_ctrl_l2_ecc register.

Note: The injection request is edge-sensitive, meaning that the request is latched on 0 to 1 transitions on the injection bit. The next time a write operation occurs, the data will be corrupted, containing either a single or double bit error as selected. When the data is read back, the ECC logic detects the single or double bit error appropriately. The injection request cannot be cancelled, and the number of injections is limited to once every 5 MPU cycles.

The system manager can also inject parity failures into the parity-protected RAM in the MPU L2 to test the parity failure interrupt handler. Set the bits of the parity fail injection register (`parityinj`) to inject parity failures.

Note: Injecting parity failures into the parity-protected RAM in the MPU L2 causes the interrupt to be raised immediately. There is no actual error injected and the data is not corrupted. Furthermore, there is no need for a memory operation to actually be performed for the interrupt to be raised.

Preloader Handoff Information

The system manager provides eight 32-bit registers to store handoff information between the preloader and the operating system. The preloader can store any information in these registers. These register contents have no impact on the state of the HPS hardware. When the operating system kernel boots, it retrieves the information by reading the preloader to OS handoff information register array. These registers are reset only by a cold reset.

Clocks

The system manager is driven by a clock generated by the clock manager.

Related Information

Clock Manager on page 2-1
For more information, refer to the Clock Manager chapter in the Cyclone V Device Handbook, Volume 3.

Resets

The system manager receives two reset signals from the reset manager. The `sys_manager_rst_n` signal is driven on a cold or warm reset and the `sys_manager_cold_rst_n` signal is driven only on a cold reset. This function allows the system manager to reset some CSR fields on either a cold or warm reset and others only on a cold reset.

wddbg

Controls the behavior of the L4 watchdogs when the CPUs are in debug mode. These control registers are used to drive the pause input signal of the L4 watchdogs. Note that the watchdogs built into the MPU automatically are paused when their associated CPU enters debug mode. Only reset by a cold reset.

Module Instance	Base Address	Register Address
sysmgr	0xFFD08000	0xFFD08010

Offset: 0x10

Access: RW

Bit Fields

Reserved						pincsel RO 0x0		pinbsel RO 0x0			csel RO 0x0		bsel RO 0x0		

bootinfo Fields

Bit	Name	Description	Access	Reset
9:8	pincsel	Specifies the sampled value of the HPS CSEL pins. The value of HPS CSEL pins are sampled upon deassertion of cold reset.	RO	0x0
7:5	pinbsel	Specifies the sampled value of the HPS BSEL pins. The value of HPS BSEL pins are sampled upon deassertion of cold reset.	RO	0x0
4:3	csel	The clock select field specifies clock information for booting. The clock select encoding is a function of the CSEL value. The clock select field is read by the Boot ROM code on a cold or warm reset when booting from a flash device to get information about how to setup the HPS clocking to boot from the specified clock device. The encoding of the clock select field is specified by the enum associated with this field. The HPS CSEL pins value are sampled upon deassertion of cold reset. **Value** — **Description** 0x0 — QSPI device clock is osc1_clk divided by 4, SD/MMC device clock is osc1_clk divided by 4, NAND device operation is osc1_clk divided by 25 0x1 — QSPI device clock is osc1_clk divided by 2, SD/MMC device clock is osc1_clk divided by 1, NAND device operation is osc1_clk multiplied by 20/25 0x2 — QSPI device clock is osc1_clk divided by 1, SD/MMC device clock is osc1_clk divided by 2, NAND device operation is osc1_clk multiplied by 10/25 0x3 — QSPI device clock is osc1_clk multiplied by 2, SD/MMC device clock is osc1_clk divided by 4, NAND device operation is osc1_clk multiplied by 5/25	RO	0x0

Bit	Name	Description	Access	Reset
2:0	`bsel`	The boot select field specifies the boot source. It is read by the Boot ROM code on a cold or warm reset to determine the boot source. The HPS BSEL pins value are sampled upon deassertion of cold reset. **Value** **Description** 0x0 Reserved 0x1 FPGA (HPS2FPGA Bridge) 0x2 NAND Flash (1.8v) 0x3 NAND Flash (3.0v) 0x4 SD/MMC External Transceiver (1.8v) 0x5 SD/MMC Internal Transceiver (3.0v) 0x6 QSPI Flash (1.8v) 0x7 QSPI Flash (3.0v)	RO	0x0

hpsinfo

Provides information about the HPS capabilities.

FPGA Interface Group Register Descriptions

Registers used to enable/disable interfaces between the FPGA and HPS. Required for either of the following situations:[list][*]Interfaces that cannot be disabled by putting an HPS module associated with the interface into reset.[*]HPS modules that accept signals from the FPGA fabric and those signals might interfere with the normal operation of the module.[/list]. All registers are only reset by a cold reset (ignore warm reset).

Offset: 0x20

gbl on page 5-29
Used to disable all interfaces between the FPGA and HPS.

indiv on page 5-30
Used to disable individual interfaces between the FPGA and HPS.

module on page 5-33
Used to disable signals from the FPGA fabric to individual HPS modules.

gbl

Used to disable all interfaces between the FPGA and HPS.

Module Instance	Base Address	Register Address

gbl Fields

Bit	Name	Description	Access	Reset
0	intf	Used to disable all interfaces between the FPGA and HPS. Software must ensure that all interfaces between the FPGA and HPS are inactive before disabling them. **Value** — **Description** 0x0 — All interfaces between FPGA and HPS are disabled. 0x1 — Interfaces between FPGA and HPS are not all disabled. Interfaces can be indivdually disabled by putting the HPS module associated with the interface in reset using registers in the Reset Manager or by using registers in this register group of the System Manager for interfaces without an associated module.	RW	0x1

indiv

Used to disable individual interfaces between the FPGA and HPS.

Module Instance	Base Address	Register Address

indiv Fields

Bit	Name	Description	Access	Reset
7	`crosstrigintf`	Used to disable the FPGA Fabric from sending triggers to HPS debug logic. Note that this doesn't prevent the HPS debug logic from sending triggers to the FPGA Fabric. **Value** **Description** 0x0 FPGA Fabric cannot send triggers. 0x1 FPGA Fabric can send triggers.	`RW`	`0x1`
6	`stmeventintf`	Used to disable the STM event interface. This interface allows logic in the FPGA fabric to trigger events to the STM debug module in the HPS. **Value** **Description** 0x0 STM event interface is disabled. Logic in the FPGA fabric cannot trigger STM events. 0x1 STM event interface is enabled. Logic in the FPGA fabric can trigger STM events.	`RW`	`0x1`
4	`traceintf`	Used to disable the trace interface. This interface allows the HPS debug logic to send trace data to logic in the FPGA fabric. **Value** **Description** 0x0 Trace interface is disabled. HPS debug logic cannot send trace data to the FPGA fabric. 0x1 Trace interface is enabled. Other registers in the HPS debug logic must be programmmed to actually send trace data to the FPGA fabric.	`RW`	`0x1`

Bit	Name	Description	Access	Reset
3	`bscanintf`	Used to disable the boundary-scan interface. This interface allows the FPGA JTAG TAP controller to execute boundary-scan instructions such as SAMPLE/PRELOAD, EXTEST, and HIGHZ. The boundary-scan interface must be enabled before attempting to send the boundary-scan instructions to the FPGA JTAG TAP controller. **Value** — **Description** 0x0 — Boundary-scan interface is disabled. Execution of boundary-scan instructions in the FPGA JTAG TAP controller is unsupported and produces undefined results. 0x1 — Boundary-scan interface is enabled. Execution of the boundary-scan instructions in the FPGA JTAG TAP controller is supported.	RW	0x1
2	`configiointf`	Used to disable the CONFIG_IO interface. This interface allows the FPGA JTAG TAP controller to execute the CONFIG_IO instruction and configure all device I/Os (FPGA and HPS). This is typically done before executing boundary-scan instructions. The CONFIG_IO interface must be enabled before attempting to send the CONFIG_IO instruction to the FPGA JTAG TAP controller. **Value** — **Description** 0x0 — CONFIG_IO interface is disabled. Execution of the CONFIG_IO instruction in the FPGA JTAG TAP controller is unsupported and produces undefined results. 0x1 — CONFIG_IO interface is enabled. Execution of the CONFIG_IO instruction in the FPGA JTAG TAP controller is supported.	RW	0x1
1	`jtagenintf`	Used to disable the JTAG enable interface. This interface allows logic in the FPGA fabric to disable the HPS JTAG operation. **Value** — **Description** 0x0 — JTAG enable interface is disabled. Logic in the FPGA fabric cannot disable the HPS JTAG. 0x1 — JTAG enable interface is enabled. Logic in the FPGA fabric can disable the HPS JTAG.	RW	0x1

Bit	Name	Description	Access	Reset
0	`rstreqintf`	Used to disable the reset request interface. This interface allows logic in the FPGA fabric to request HPS resets. This field disables the following reset request signals from the FPGA fabric to HPS:[list][*]f2h_cold_rst_req_n - Triggers a cold reset of the HPS[*]f2h_warm_rst_req_n - Triggers a warm reset of the HPS[*]f2h_dbg_rst_req_n - Triggers a debug reset of the HPS[/list] **Value** **Description** 0x0 Reset request interface is disabled. Logic in the FPGA fabric cannot reset the HPS. 0x1 Reset request interface is enabled. Logic in the FPGA fabric can reset the HPS.	RW	0x1

module

Used to disable signals from the FPGA fabric to individual HPS modules.

Module Instance	Base Address	Register Address

Bit	Name	Description	Access	Reset
0	fpgajtagen	Controls whether FPGA JTAG pins or Scan Manager drives JTAG signals to the FPGA. Only reset by a cold reset (ignores warm reset). **Value** **Description** 0x0 FPGA JTAG pins drive JTAG signals to FPGA 0x1 Scan Manager drives JTAG signals to FPGA	RW	0x0

Freeze Control Group Register Descriptions

Registers used to generate HPS IO freeze signals. All registers are only reset by a cold reset (ignore warm reset).

Offset: 0x40

vioctrl on page 5-36
Used to drive freeze signals to HPS VIO banks. The register array index corresponds to the freeze channel. Freeze channel 0 provides freeze signals to VIO bank 0 and 1. Freeze channel 1 provides freeze signals to VIO bank 2 and 3. Only drives freeze signals when SRC.VIO1 is set to SW. Freeze channel 2 provides freeze signals to VIO bank 4. All fields are only reset by a cold reset (ignore warm reset). The following equation determines when the weak pullup resistor is enabled: enabled = ~wkpullup | (CFF & cfg & tristate) where CFF is the value of weak pullup as set by IO configuration

hioctrl on page 5-37
Used to drive freeze signals to HPS HIO bank (DDR SDRAM). All fields are only reset by a cold reset (ignore warm reset). The following equation determines when the weak pullup resistor is enabled: enabled = ~wkpullup | (CFF & cfg & tristate) where CFF is the value of weak pullup as set by IO configuration

src on page 5-40
Contains register field to choose between software state machine (vioctrl array index [1] register) or hardware state machine in the Freeze Controller as the freeze signal source for VIO channel 1. All fields are only reset by a cold reset (ignore warm reset).

hwctrl on page 5-40

Activate freeze or thaw operations on VIO channel 1 (HPS IO bank 2 and bank 3) and monitor for completeness and the current state. These fields interact with the hardware state machine in the Freeze Controller. These fields can be accessed independent of the value of SRC1.VIO1 although they only have an effect on the VIO channel 1 freeze signals when SRC1.VIO1 is setup to have the hardware state machine be the freeze signal source. All fields are only reset by a cold reset (ignore warm reset).

vioctrl

Used to drive freeze signals to HPS VIO banks. The register array index corresponds to the freeze channel. Freeze channel 0 provides freeze signals to VIO bank 0 and 1. Freeze channel 1 provides freeze signals to VIO bank 2 and 3. Only drives freeze signals when SRC.VIO1 is set to SW. Freeze channel 2 provides freeze signals to VIO bank 4. All fields are only reset by a cold reset (ignore warm reset). The following equation determines when the weak pullup resistor is enabled: enabled = ~wkpullup | (CFF & cfg & tristate) where CFF is the value of weak pullup as set by IO configuration

Boot ROM Code Register Group Register Descriptions

Registers used by the Boot ROM code. All fields are only reset by a cold reset (ignore warm reset).

Offset: 0xc0

ctrl on page 5-51
Contains information used to control Boot ROM code.

cpu1startaddr on page 5-53
When CPU1 is released from reset and the Boot ROM is located at the CPU1 reset exception address (the typical case), the Boot ROM reset handler code reads the address stored in this register and jumps it to hand off execution to user software.

initswstate on page 5-53
The preloader software (loaded by the Boot ROM) writes the magic value 0x49535756 (ISWV in ASCII) to this register when it has reached a valid state.

initswlastld on page 5-54
Contains the index of the last preloader software image loaded by the Boot ROM from the boot device.

bootromswstate on page 5-54
32-bits general purpose register used by the Boot ROM code. Actual usage is defined in the Boot ROM source code.

Warm Boot from On-Chip RAM Group Register Descriptions on page 5-55
Registers used by the Boot ROM code to support booting from the On-chip RAM on a warm reset. All these registers must be written by user software before a warm reset occurs to make use of this feature.

ctrl

Contains information used to control Boot ROM code.

Module Instance	Base Address	Register Address

Warm Boot from On-Chip RAM Group Register Descriptions

Registers used by the Boot ROM code to support booting from the On-chip RAM on a warm reset. All these registers must be written by user software before a warm reset occurs to make use of this feature.

Offset: 0x20

enable on page 5-55
Enables or disables the warm reset from On-chip RAM feature.

datastart on page 5-56
Offset into On-chip RAM of the start of the region for CRC validation

length on page 5-56
Length of region in On-chip RAM for CRC validation.

execution on page 5-57
Offset into On-chip RAM to enter to on a warm boot.

crc on page 5-58
Length of region in On-chip RAM for CRC validation.

enable

Enables or disables the warm reset from On-chip RAM feature.

Module Instance	Base Address	Register Address
sysmgr	0xFFD08000	0xFFD080E0

Offset: 0xE0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
magic RW 0x0															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
magic RW 0x0															

enable Fields

Bit	Name	Description	Access	Reset
31:0	`magic`	Controls whether Boot ROM will attempt to boot from the contents of the On-chip RAM on a warm reset. When this feature is enabled, the Boot ROM code will not configure boot IOs, the pin mux, or clocks. Note that the enable value is a 32-bit magic value (provided by the enum). **Value** — **Description** 0x0 — Boot ROM code will not attempt to boot from On-chip RAM on a warm reset 0xae9efebc — Boot ROM code will attempt to boot from On-chip RAM on a warm reset	`RW`	`0x0`

datastart

Offset into On-chip RAM of the start of the region for CRC validation

Module Instance	Base Address	Register Address
`sysmgr`	`0xFFD08000`	`0xFFD080E4`

Offset: `0xE4`

Access: `RW`

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
offset RW 0x0															

datastart Fields

Bit	Name	Description	Access	Reset
15:0	`offset`	Contains the byte offset into the On-chip RAM of the start of the On-chip RAM region for the warm boot CRC validation. The offset must be an integer multiple of 4 (i.e. aligned to a word). The Boot ROM code will set the top 16 bits to 0xFFFF and clear the bottom 2 bits.	`RW`	`0x0`

length

Length of region in On-chip RAM for CRC validation.

Module Instance	Base Address	Register Address
sysmgr	0xFFD08000	0xFFD080E8

Offset: 0xE8

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
size RW 0x0															

length Fields

Bit	Name	Description	Access	Reset
15:0	size	Contains the length (in bytes) of the region in the On-chip RAM for the warm boot CRC validation. If the length is 0, the Boot ROM won't perform CRC calculation and CRC check to avoid overhead caused by CRC validation. If the START + LENGTH exceeds the maximum offset into the On-chip RAM, the Boot ROM won't boot from the On-chip RAM. The length must be an integer multiple of 4. The Boot ROM code will clear the top 16 bits and the bottom 2 bits.	RW	0x0

execution

Offset into On-chip RAM to enter to on a warm boot.

Module Instance	Base Address	Register Address
sysmgr	0xFFD08000	0xFFD080EC

Offset: 0xEC

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
offset RW 0x0															

execution Fields

Bit	Name	Description	Access	Reset
15:0	`offset`	Contains the byte offset into the On-chip RAM that the Boot ROM will jump to if the CRC validation succeeds. The Boot ROM code will set the top 16 bits to 0xFFFF.	`RW`	`0x0`

crc

Length of region in On-chip RAM for CRC validation.

Module Instance	Base Address	Register Address
`sysmgr`	`0xFFD08000`	`0xFFD080F0`

Offset: `0xF0`

Access: `RW`

<tr><td colspan="16">expected
RW 0xE763552A</td></tr>
</table>

crc Fields

Bit	Name	Description	Access	Reset
31:0	`expected`	Contains the expected CRC of the region in the On-chip RAM.The Boot ROM code calculates the actual CRC for all bytes in the region specified by the DATA START an LENGTH registers. The contents of the EXECUTION register (after it has been read and modified by the Boot ROM code) is also included in the CRC calculation. The contents of the EXECUTION register is added to the CRC accumulator a byte at a time starting with the least significant byte. If the actual CRC doesn't match the expected CRC value in this register, the Boot ROM won't boot from the On-chip RAM. The CRC is a standard CRC32 with the polynomial: x^32 + x^26 + x^23 + x^22 + x^16 + x^12 + x^11 + x^10 + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1 There is no reflection of the bits and the initial value of the remainder is 0xFFFFFFFF and the final value is exclusive ORed with 0xFFFFFFFF.	`RW`	`0xE763552A`

Boot ROM Hardware Register Group Register Descriptions

Registers used by the Boot ROM hardware, not the code within it.

Offset: `0x100`

ctrl on page 5-59
Controls behavior of Boot ROM hardware. All fields are only reset by a cold reset (ignore warm reset).

ctrl

Controls behavior of Boot ROM hardware. All fields are only reset by a cold reset (ignore warm reset).

3:0	`arcache_0`	Specifies the value of the module ARCACHE signal. **Value** **Description** 0x0 Noncacheable and nonbufferable. 0x1 Bufferable only. 0x2 Cacheable, but do not allocate. 0x3 Cacheable and bufferable, but do not allocate. 0x4 Reserved. 0x5 Reserved. 0x6 Cacheable write-through, allocate on reads only. 0x7 Cacheable write-back, allocate on reads only. 0x8 Reserved. 0x9 Reserved. 0xa Cacheable write-through, allocate on writes only. 0xb Cacheable write-back, allocate on writes only. 0xc Reserved. 0xd Reserved. 0xe Cacheable write-through, allocate on both reads and writes. 0xf Cacheable write-back, allocate on both reads and writes.	`RW`	`0x0`

USB Controller Group Register Descriptions

Registers related to USB Controllers which aren't located inside the USB controllers themselves.

Offset: `0x118`

l3master on page 5-65
Controls the L3 master HPROT AHB-Lite signal. These register bits should be updated only during system initialization prior to removing the peripheral from reset. They may not be changed dynamically during peripheral operation All fields are reset by a cold or warm reset.

l3master

Bit	Name	Description	Access	Reset
1	`hprotdata_1`	Specifies if the L3 master access is for data or opcode for the USB modules. The field array index corresponds to the USB index. **Value** **Description** 0x0 Opcode fetch 0x1 Data access	RW	0x1
0	`hprotdata_0`	Specifies if the L3 master access is for data or opcode for the USB modules. The field array index corresponds to the USB index. **Value** **Description** 0x0 Opcode fetch 0x1 Data access	RW	0x1

ECC Management Register Group Register Descriptions

ECC error status and control for all ECC-protected HPS RAM blocks.

Offset: `0x140`

l2 on page 5-68
This register is used to enable ECC on the L2 Data RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

ocram on page 5-69
This register is used to enable ECC on the On-chip RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

usb0 on page 5-70
This register is used to enable ECC on the USB0 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

usb1 on page 5-71
This register is used to enable ECC on the USB1 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

emac0 on page 5-72
This register is used to enable ECC on the EMAC0 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

emac1 on page 5-73
This register is used to enable ECC on the EMAC1 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

dma on page 5-75
This register is used to enable ECC on the DMA RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

can0 on page 5-76
This register is used to enable ECC on the CAN0 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

can1 on page 5-77
This register is used to enable ECC on the CAN1 RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

nand on page 5-78
This register is used to enable ECC on the NAND RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

qspi on page 5-80
This register is used to enable ECC on the QSPI RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

sdmmc on page 5-80
This register is used to enable ECC on the SDMMC RAM.ECC errors can be injected into the write path using bits in this register. Only reset by a cold reset (ignores warm reset).

l2

This register is used to enable ECC on the L2 Data RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

Bit	Name	Description	Access	Reset
9	wrfifoserr	This bit is an interrupt status bit for NAND WRFIFO RAM ECC single, correctable error. It is set by hardware when single, correctable error occurs in NAND WRFIFO RAM. Software needs to write 1 into this bit to clear the interrupt status.	RW	0x0
8	eccbufderr	This bit is an interrupt status bit for NAND ECCBUFFER RAM ECC double bit, non-correctable error. It is set by hardware when double bit, non-correctable error occurs in NAND ECCBUFFER RAM. Software needs to write 1 into this bit to clear the interrupt status.	RW	0x0
7	eccbufserr	This bit is an interrupt status bit for NAND ECCBUFFER RAM ECC single, correctable error. It is set by hardware when single, correctable error occurs in NAND ECCBUFFER RAM. Software needs to write 1 into this bit to clear the interrupt status.	RW	0x0
6	rdfifoinjd	Changing this bit from zero to one injects a double, non-correctable error into the NAND RDFIFO RAM. This only injects one double bit error into the NAND RDFIFO RAM.	RW	0x0
5	rdfifoinjs	Changing this bit from zero to one injects a single, correctable error into the NAND RDFIFO RAM. This only injects one error into the NAND RDFIFO RAM.	RW	0x0
4	wrfifoinjd	Changing this bit from zero to one injects a double, non-correctable error into the NAND WRFIFO RAM. This only injects one double bit error into the NAND WRFIFO RAM.	RW	0x0
3	wrfifoinjs	Changing this bit from zero to one injects a single, correctable error into the NAND WRFIFO RAM. This only injects one error into the NAND WRFIFO RAM.	RW	0x0
2	eccbufinjd	Changing this bit from zero to one injects a double, non-correctable error into the NAND ECCBUFFER RAM. This only injects one double bit error into the NAND ECCBUFFER RAM.	RW	0x0
1	eccbufinjs	Changing this bit from zero to one injects a single, correctable error into the NAND ECCBUFFER RAM. This only injects one error into the NAND ECCBUFFER RAM.	RW	0x0
0	en	Enable ECC for NAND RAM	RW	0x0

qspi

This register is used to enable ECC on the QSPI RAM. ECC errors can be injected into the write path using bits in this register. This register contains interrupt status of the ECC single/double bit error. Only reset by a cold reset (ignores warm reset).

Pin Mux Control Group Register Descriptions

Controls Pin Mux selections NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

Offset: `0x400`

EMACIO0 on page 5-101
This register is used to control the peripherals connected to emac0_tx_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO1 on page 5-102
This register is used to control the peripherals connected to emac0_tx_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO2 on page 5-103
This register is used to control the peripherals connected to emac0_tx_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO3 on page 5-103
This register is used to control the peripherals connected to emac0_tx_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO4 on page 5-104
This register is used to control the peripherals connected to emac0_tx_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO5 on page 5-104
This register is used to control the peripherals connected to emac0_rx_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO6 on page 5-105
This register is used to control the peripherals connected to emac0_mdio Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO7 on page 5-105
This register is used to control the peripherals connected to emac0_mdc Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO8 on page 5-106
This register is used to control the peripherals connected to emac0_rx_ctl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO9 on page 5-107
This register is used to control the peripherals connected to emac0_tx_ctl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO10 on page 5-107
This register is used to control the peripherals connected to emac0_rx_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO11 on page 5-108
This register is used to control the peripherals connected to emac0_rx_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO12 on page 5-109
This register is used to control the peripherals connected to emac0_rx_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO13 on page 5-109
This register is used to control the peripherals connected to emac0_rx_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO14 on page 5-110
This register is used to control the peripherals connected to emac1_tx_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO15 on page 5-110
This register is used to control the peripherals connected to emac1_tx_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO16 on page 5-111
This register is used to control the peripherals connected to emac1_tx_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO17 on page 5-112
This register is used to control the peripherals connected to emac1_tx_ctl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO18 on page 5-112
This register is used to control the peripherals connected to emac1_rx_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO19 on page 5-113
This register is used to control the peripherals connected to emac1_rx_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO0 on page 5-113
This register is used to control the peripherals connected to sdmmc_cmd Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO1 on page 5-114
This register is used to control the peripherals connected to sdmmc_pwren Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO2 on page 5-115
This register is used to control the peripherals connected to sdmmc_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO3 on page 5-115
This register is used to control the peripherals connected to sdmmc_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO4 on page 5-116
This register is used to control the peripherals connected to sdmmc_d4 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO5 on page 5-116
This register is used to control the peripherals connected to sdmmc_d5 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO6 on page 5-117
This register is used to control the peripherals connected to sdmmc_d6 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO7 on page 5-117
This register is used to control the peripherals connected to sdmmc_d7 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO8 on page 5-118
This register is used to control the peripherals connected to sdmmc_clk_in Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO9 on page 5-119
This register is used to control the peripherals connected to sdmmc_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO10 on page 5-119
This register is used to control the peripherals connected to sdmmc_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

FLASHIO11 on page 5-120
This register is used to control the peripherals connected to sdmmc_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO0 on page 5-120
This register is used to control the peripherals connected to trace_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO1 on page 5-121
This register is used to control the peripherals connected to trace_d0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO2 on page 5-122
This register is used to control the peripherals connected to trace_d1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO3 on page 5-122
This register is used to control the peripherals connected to trace_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO4 on page 5-123
This register is used to control the peripherals connected to trace_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO5 on page 5-123
This register is used to control the peripherals connected to trace_d4 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO6 on page 5-124
This register is used to control the peripherals connected to trace_d5 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO7 on page 5-125
This register is used to control the peripherals connected to trace_d6 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO8 on page 5-125
This register is used to control the peripherals connected to trace_d7 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO9 on page 5-126
This register is used to control the peripherals connected to spim0_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO10 on page 5-126
This register is used to control the peripherals connected to spim0_mosi Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO11 on page 5-127
This register is used to control the peripherals connected to spim0_miso Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO12 on page 5-128
This register is used to control the peripherals connected to spim0_ss0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO13 on page 5-128
This register is used to control the peripherals connected to uart0_rx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO14 on page 5-129
This register is used to control the peripherals connected to uart0_tx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO15 on page 5-129
This register is used to control the peripherals connected to i2c0_sda Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO16 on page 5-130
This register is used to control the peripherals connected to i2c0_scl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO17 on page 5-131
This register is used to control the peripherals connected to can0_rx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO18 on page 5-131
This register is used to control the peripherals connected to can0_tx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO19 on page 5-132
This register is used to control the peripherals connected to spis1_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO20 on page 5-132
This register is used to control the peripherals connected to spis1_mosi Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO21 on page 5-133
This register is used to control the peripherals connected to spis1_miso Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO22 on page 5-134
This register is used to control the peripherals connected to spis1_ss0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO23 on page 5-134
This register is used to control the peripherals connected to uart1_rx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO24 on page 5-135
This register is used to control the peripherals connected to uart1_tx Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO25 on page 5-135
This register is used to control the peripherals connected to i2c1_sda Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO26 on page 5-136
This register is used to control the peripherals connected to i2c1_scl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GENERALIO27 on page 5-137
This register is used to control the peripherals connected to spim0_ss0_alt Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO0 on page 5-137
This register is used to control the peripherals connected to nand_ale Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO1 on page 5-138
This register is used to control the peripherals connected to nand_ce Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO2 on page 5-138
This register is used to control the peripherals connected to nand_cle Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO3 on page 5-139
This register is used to control the peripherals connected to nand_re Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO4 on page 5-140
This register is used to control the peripherals connected to nand_rb Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO5 on page 5-140
This register is used to control the peripherals connected to nand_dq0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO6 on page 5-141
This register is used to control the peripherals connected to nand_dq1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO7 on page 5-141
This register is used to control the peripherals connected to nand_dq2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO8 on page 5-142
This register is used to control the peripherals connected to nand_dq3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO9 on page 5-143
This register is used to control the peripherals connected to nand_dq4 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO10 on page 5-143
This register is used to control the peripherals connected to nand_dq5 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO11 on page 5-144
This register is used to control the peripherals connected to nand_dq6 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO12 on page 5-144
This register is used to control the peripherals connected to nand_dq7 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO13 on page 5-145
This register is used to control the peripherals connected to nand_wp Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO14 on page 5-146
This register is used to control the peripherals connected to nand_we Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO15 on page 5-146
This register is used to control the peripherals connected to qspi_io0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO16 on page 5-147
This register is used to control the peripherals connected to qspi_io1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO17 on page 5-147
This register is used to control the peripherals connected to qspi_io2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO18 on page 5-148
This register is used to control the peripherals connected to qspi_io3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO19 on page 5-149
This register is used to control the peripherals connected to qspi_ss0 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO20 on page 5-149
This register is used to control the peripherals connected to qpsi_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED1IO21 on page 5-150
This register is used to control the peripherals connected to qspi_ss1 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO0 on page 5-150
This register is used to control the peripherals connected to emac1_mdio Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO1 on page 5-151
This register is used to control the peripherals connected to emac1_mdc Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO2 on page 5-152
This register is used to control the peripherals connected to emac1_tx_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO3 on page 5-152
This register is used to control the peripherals connected to emac1_tx_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO4 on page 5-153
This register is used to control the peripherals connected to emac1_rx_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO5 on page 5-153
This register is used to control the peripherals connected to emac1_rx_ctl Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO6 on page 5-154
This register is used to control the peripherals connected to emac1_rx_d2 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

MIXED2IO7 on page 5-155
This register is used to control the peripherals connected to emac1_rx_d3 Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX48 on page 5-155
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 48. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX49 on page 5-156
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 49. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX50 on page 5-156
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 50. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX51 on page 5-157
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 51. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX52 on page 5-157
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 52. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX53 on page 5-158
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 53. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX54 on page 5-159
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 54. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX55 on page 5-159
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 55. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX56 on page 5-160
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 56. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX57 on page 5-160
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 57. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX58 on page 5-161
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 58. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX59 on page 5-161
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 59. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX60 on page 5-162
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 60. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX61 on page 5-162
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/LoanIO 61. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX62 on page 5-163
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 62. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX63 on page 5-164
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 63. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX64 on page 5-164
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 64. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX65 on page 5-165
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 65. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX66 on page 5-165
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 66. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX67 on page 5-166
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 67. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX68 on page 5-166
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 68. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX69 on page 5-167
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 69. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLINMUX70 on page 5-167
Some GPIO/LoanIO inputs can be driven by multiple pins. This register selects the input signal for GPIO/ LoanIO 70. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX0 on page 5-168
Selection between GPIO and LoanIO output and output enable for GPIO0 and LoanIO0. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX1 on page 5-169
Selection between GPIO and LoanIO output and output enable for GPIO1 and LoanIO1. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX2 on page 5-169
Selection between GPIO and LoanIO output and output enable for GPIO2 and LoanIO2. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX3 on page 5-170
Selection between GPIO and LoanIO output and output enable for GPIO3 and LoanIO3. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX4 on page 5-170
Selection between GPIO and LoanIO output and output enable for GPIO4 and LoanIO4. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX5 on page 5-171
Selection between GPIO and LoanIO output and output enable for GPIO5 and LoanIO5. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX6 on page 5-171
Selection between GPIO and LoanIO output and output enable for GPIO6 and LoanIO6. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX7 on page 5-172
Selection between GPIO and LoanIO output and output enable for GPIO7 and LoanIO7. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX8 on page 5-173
Selection between GPIO and LoanIO output and output enable for GPIO8 and LoanIO8. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX9 on page 5-173
Selection between GPIO and LoanIO output and output enable for GPIO9 and LoanIO9. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX10 on page 5-174
Selection between GPIO and LoanIO output and output enable for GPIO10 and LoanIO10. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX11 on page 5-174
Selection between GPIO and LoanIO output and output enable for GPIO11 and LoanIO11. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX12 on page 5-175
Selection between GPIO and LoanIO output and output enable for GPIO12 and LoanIO12. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX13 on page 5-176
Selection between GPIO and LoanIO output and output enable for GPIO13 and LoanIO13. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX14 on page 5-176
Selection between GPIO and LoanIO output and output enable for GPIO14 and LoanIO14. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX15 on page 5-177
Selection between GPIO and LoanIO output and output enable for GPIO15 and LoanIO15. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX16 on page 5-177
Selection between GPIO and LoanIO output and output enable for GPIO16 and LoanIO16. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX17 on page 5-178
Selection between GPIO and LoanIO output and output enable for GPIO17 and LoanIO17. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX18 on page 5-179
Selection between GPIO and LoanIO output and output enable for GPIO18 and LoanIO18. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX19 on page 5-179
Selection between GPIO and LoanIO output and output enable for GPIO19 and LoanIO19. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX20 on page 5-180
Selection between GPIO and LoanIO output and output enable for GPIO20 and LoanIO20. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX21 on page 5-180
Selection between GPIO and LoanIO output and output enable for GPIO21 and LoanIO21. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX22 on page 5-181
Selection between GPIO and LoanIO output and output enable for GPIO22 and LoanIO22. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX23 on page 5-182
Selection between GPIO and LoanIO output and output enable for GPIO23 and LoanIO23. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX24 on page 5-182
Selection between GPIO and LoanIO output and output enable for GPIO24 and LoanIO24. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX25 on page 5-183
Selection between GPIO and LoanIO output and output enable for GPIO25 and LoanIO25. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX26 on page 5-183
Selection between GPIO and LoanIO output and output enable for GPIO26 and LoanIO26. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX27 on page 5-184
Selection between GPIO and LoanIO output and output enable for GPIO27 and LoanIO27. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX28 on page 5-185
Selection between GPIO and LoanIO output and output enable for GPIO28 and LoanIO28. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX29 on page 5-185
Selection between GPIO and LoanIO output and output enable for GPIO29 and LoanIO29. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX30 on page 5-186
Selection between GPIO and LoanIO output and output enable for GPIO30 and LoanIO30. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX31 on page 5-186
Selection between GPIO and LoanIO output and output enable for GPIO31 and LoanIO31. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX32 on page 5-187
Selection between GPIO and LoanIO output and output enable for GPIO32 and LoanIO32. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX33 on page 5-188
Selection between GPIO and LoanIO output and output enable for GPIO33 and LoanIO33. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX34 on page 5-188
Selection between GPIO and LoanIO output and output enable for GPIO34 and LoanIO34. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX35 on page 5-189
Selection between GPIO and LoanIO output and output enable for GPIO35 and LoanIO35. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX36 on page 5-189
Selection between GPIO and LoanIO output and output enable for GPIO36 and LoanIO36. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX37 on page 5-190
Selection between GPIO and LoanIO output and output enable for GPIO37 and LoanIO37. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX38 on page 5-191
Selection between GPIO and LoanIO output and output enable for GPIO38 and LoanIO38. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX39 on page 5-191
Selection between GPIO and LoanIO output and output enable for GPIO39 and LoanIO39. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX40 on page 5-192
Selection between GPIO and LoanIO output and output enable for GPIO40 and LoanIO40. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX41 on page 5-192
Selection between GPIO and LoanIO output and output enable for GPIO41 and LoanIO41. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX42 on page 5-193
Selection between GPIO and LoanIO output and output enable for GPIO42 and LoanIO42. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX43 on page 5-194
Selection between GPIO and LoanIO output and output enable for GPIO43 and LoanIO43. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX44 on page 5-194
Selection between GPIO and LoanIO output and output enable for GPIO44 and LoanIO44. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX45 on page 5-195
Selection between GPIO and LoanIO output and output enable for GPIO45 and LoanIO45. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX46 on page 5-195
Selection between GPIO and LoanIO output and output enable for GPIO46 and LoanIO46. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX47 on page 5-196
Selection between GPIO and LoanIO output and output enable for GPIO47 and LoanIO47. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX48 on page 5-197
Selection between GPIO and LoanIO output and output enable for GPIO48 and LoanIO48. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX49 on page 5-197
Selection between GPIO and LoanIO output and output enable for GPIO49 and LoanIO49. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX50 on page 5-198
Selection between GPIO and LoanIO output and output enable for GPIO50 and LoanIO50. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX51 on page 5-198
Selection between GPIO and LoanIO output and output enable for GPIO51 and LoanIO51. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX52 on page 5-199
Selection between GPIO and LoanIO output and output enable for GPIO52 and LoanIO52. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX53 on page 5-200
Selection between GPIO and LoanIO output and output enable for GPIO53 and LoanIO53. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX54 on page 5-200
Selection between GPIO and LoanIO output and output enable for GPIO54 and LoanIO54. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX55 on page 5-201
Selection between GPIO and LoanIO output and output enable for GPIO55 and LoanIO55. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX56 on page 5-201
Selection between GPIO and LoanIO output and output enable for GPIO56 and LoanIO56. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX57 on page 5-202
Selection between GPIO and LoanIO output and output enable for GPIO57 and LoanIO57. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX58 on page 5-203
Selection between GPIO and LoanIO output and output enable for GPIO58 and LoanIO58. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX59 on page 5-203
Selection between GPIO and LoanIO output and output enable for GPIO59 and LoanIO59. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX60 on page 5-204
Selection between GPIO and LoanIO output and output enable for GPIO60 and LoanIO60. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX61 on page 5-204
Selection between GPIO and LoanIO output and output enable for GPIO61 and LoanIO61. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX62 on page 5-205
Selection between GPIO and LoanIO output and output enable for GPIO62 and LoanIO62. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX63 on page 5-206
Selection between GPIO and LoanIO output and output enable for GPIO63 and LoanIO63. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX64 on page 5-206
Selection between GPIO and LoanIO output and output enable for GPIO64 and LoanIO64. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX65 on page 5-207
Selection between GPIO and LoanIO output and output enable for GPIO65 and LoanIO65. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX66 on page 5-207
Selection between GPIO and LoanIO output and output enable for GPIO66 and LoanIO66. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX67 on page 5-208
Selection between GPIO and LoanIO output and output enable for GPIO67 and LoanIO67. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX68 on page 5-209
Selection between GPIO and LoanIO output and output enable for GPIO68 and LoanIO68. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX69 on page 5-209
Selection between GPIO and LoanIO output and output enable for GPIO69 and LoanIO69. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX70 on page 5-210
Selection between GPIO and LoanIO output and output enable for GPIO70 and LoanIO70. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

NANDUSEFPGA on page 5-210
Selection between HPS Pins and FPGA Interface for NAND signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

RGMII1USEFPGA on page 5-211
Selection between HPS Pins and FPGA Interface for RGMII1 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

I2C0USEFPGA on page 5-212
Selection between HPS Pins and FPGA Interface for I2C0 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

RGMII0USEFPGA on page 5-212
Selection between HPS Pins and FPGA Interface for RGMII0 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

I2C3USEFPGA on page 5-213
Selection between HPS Pins and FPGA Interface for I2C3 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

I2C2USEFPGA on page 5-213
Selection between HPS Pins and FPGA Interface for I2C2 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

I2C1USEFPGA on page 5-214
Selection between HPS Pins and FPGA Interface for I2C1 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

SPIM1USEFPGA on page 5-214
Selection between HPS Pins and FPGA Interface for SPIM1 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

SPIM0USEFPGA on page 5-215
Selection between HPS Pins and FPGA Interface for SPIM0 signals. Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

EMACIO0

This register is used to control the peripherals connected to emac0_tx_clk Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

GPLMUX6

Selection between GPIO and LoanIO output and output enable for GPIO6 and LoanIO6. These signals drive the Pin Mux. The Pin Mux must be configured to use GPIO/LoanIO in addition to these settings

Only reset by a cold reset (ignores warm reset). NOTE: These registers should not be modified after IO configuration.There is no support for dynamically changing the Pin Mux selections.

Scan Manager 6

2014.06.30

cv_54015 Subscribe Send Feedback

The scan manager is used to configure and manage the HPS I/O pins, and communicate with the FPGA JTAG test access port (TAP) controller. The scan manager drives the HPS I/O scan chains to configure the I/O bank properties before the pins are used by the peripherals in HPS. The scan manager can also optionally communicate with the FPGA JTAG TAP controller to send commands for purposes such as managing cyclic redundancy check (CRC) errors detected by the FPGA control block. When the scan manager communicates with the FPGA JTAG TAP controller, input on the FPGA JTAG pins is ignored.

The scan manager contains an ARM® JTAG Access Port (JTAG-AP). The JTAG-AP implements a multiple scan-chain JTAG master interface. One scan chain connects to the FPGA JTAG and uses the standard JTAG signals. Four other scan chains connect to the HPS I/O banks, using the JTAG clock and data outputs as a parallel-to-serial converter.

Related Information

http://infocenter.arm.com/

For more information about the ARM JTAG-AP, refer to the *DAP Components* chapter of the *CoreSight SoC Technical Reference Manual*, which you can download from the ARM Infocenter website.

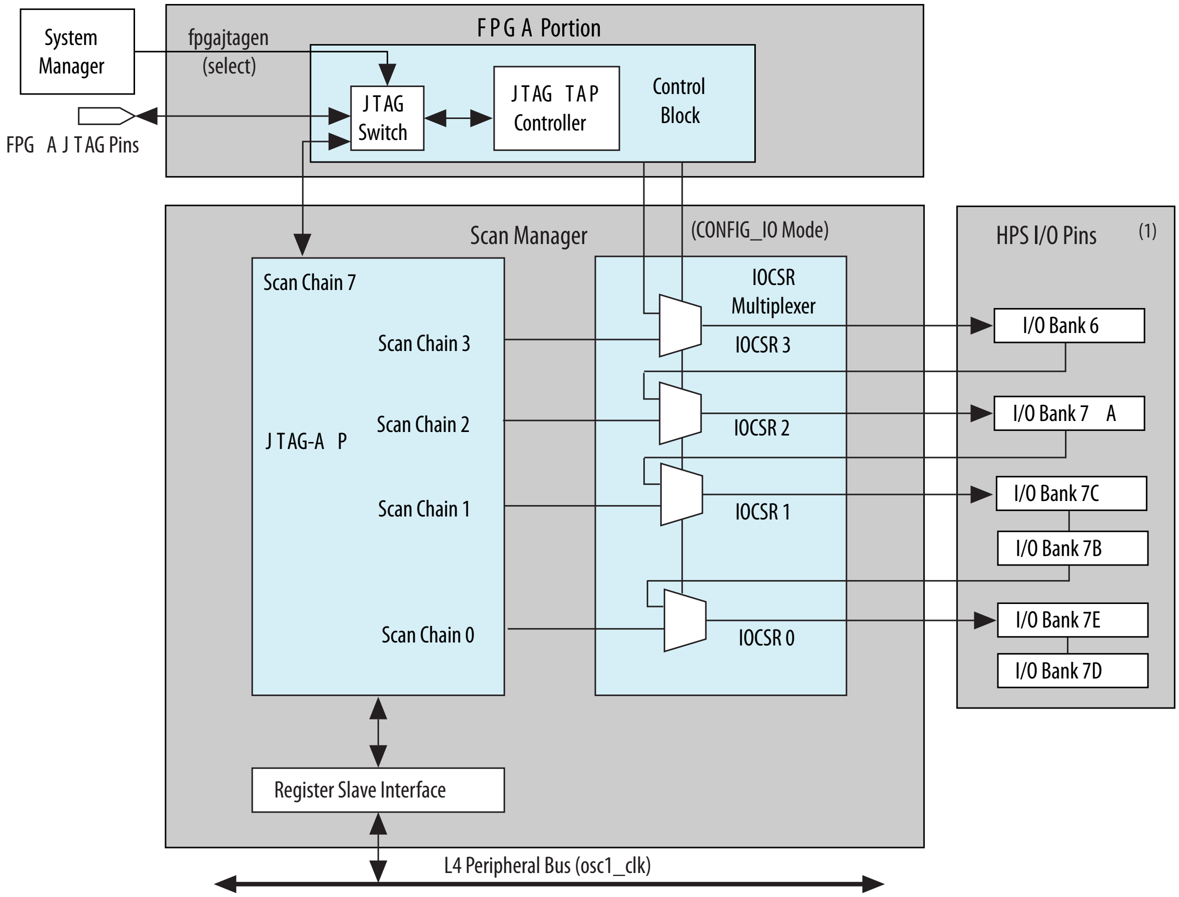
Features of the Scan Manager

- Drives all the I/O scan chains for HPS I/O banks
- Allows the HPS to access the FPGA JTAG TAP controller

Scan Manager Block Diagram and System Integration

Figure 6-1: Scan Manager Block Diagram

[1] Not all devices contain all the banks depicted.



The processor accesses the scan manager through the register slave interface connected to the level 4 (L4) peripheral bus.

ARM JTAG-AP Signal Use in the Scan Manager

The following table describes how the ARM JTAG-AP signals are connected in the scan manager. These signals are internal to the scan manager, are provided here for reference only, and are not shown in the preceding figure. The signal, register, and field names listed in the table match the names used in the *ARM Debug Interface v5 Architecture Specification*.

Signal	Direction	Implementation
`SRSTCONNECTED[7:0]`	Input	Tied to 0. The read-only `SRSTCONNECTED` field in the `CSW` register always reads as 0.

Signal	Direction	Implementation
PORTCONNECTED[7:0]	Input	Tied to 0x8F, which connects only ports 0-3 and 7. The read-only PORTCONNECTED field in the CSW register reads as 1 when the PORTSEL register is written with a value that enables one of the connected ports, and reads as 0 otherwise.
PORTENABLED[7:0]	Input	Tied to 0x8F, so all connected ports are always considered powered on. The ARM JTAG AP PSTA register is not supported. Software does not need to monitor the status of ports 0-3 because they are always on. For port 7, software can read the mode field of the stat register in the FPGA manager to determine the FPGA power status.
nSRSTOUT[7:0]	Output	Not connected. Writing to the SRST_OUT field of the CSW register has no effect.
nTRST*[7:0]	Output	nTRST*[7] is connected to the FPGA JTAG TAP controller and nTRST*[6:0] are not connected. Writing to the TRST_OUT field of the CSW register (the trst bit of the stat register in the scan manager) has an effect only when port 7 is enabled by software. For details, refer to *"Communicating with the JTAG TAP Controller"*.

  For detailed information about the ARM JTAG-AP CSW, PORTSEL, and PSTA registers, refer to the *DAP Components* chapter of the *CoreSight SoC Technical Reference Manual*, which you can download from the ARM Infocenter website.

ARM JTAG-AP Scan Chains

The ARM JTAG-AP supports up to eight scan chains. The scan manager uses only scan chains 0, 1, 2, 3, and 7.

Scan chain 7 of the JTAG-AP connects to FPGA JTAG TAP controller. When the system manager undergoes a cold reset, this connection is disabled and the FPGA JTAG pins are connected to the FPGA JTAG TAP controller. You can configure the system manager to enable the connection, which allows software running on the HPS to communicate with the FPGA JTAG TAP controller. In this case, software can send JTAG commands (such as the SHIFT_EDERROR_REG JTAG instruction) to the FPGA JTAG and get responses to determine details about CRC errors detected by the control block when the FPGA fabric is in user mode. Through the FPGA manager, software can determine that a CRC error was detected. For more information about the TAP controller, refer to the *Communicating with the JTAG TAP Controller* section of this chapter.

Scan chains 0 to 3 of the JTAG-AP connect to the configuration information in the HPS I/O scan chain banks through the I/O configuration shift register (IOCSR) multiplexer. For more information, refer to the *Configuring HPS I/O Scan Chains* section of this chapter.

Note: The I/O scan chains do not use the JTAG protocol. The scan manager uses the JTAG-AP as a parallel-to-serial converter for the I/O scan chains. The I/O scan chains are connected only to the serial output data (`TDI` JTAG signal) and serial clock (`TCK` JTAG signal).

The HPS I/O pins are divided into six banks. Each I/O bank is either a vertical (VIO) or horizontal (HIO) I/O, based on its location on the die.

Table 6-1: Bank Usage of IOCSR Scan Chains

The following table shows the mapping of the IOCSR scan chains to the I/O banks.

IOCSR Scan Chain	Bank Type	HPS I/O Bank	Usage
0	VIO	I/O bank 7D and I/O bank 7E	EMAC
1	VIO	I/O bank 7B and I/O bank 7C	SD/MMC, NAND, and quad SPI
2	VIO	I/O bank 7A	Trace, SPI, UART, I^{2}C, and CAN
3	HIO	I/O bank 6	SDRAM DDR

When the FPGA JTAG TAP controller is in `CONFIG_IO` mode, the controller can override the scan manager JTAG-AP and configure the HPS I/O pins. For more information, refer to the *Configuring HPS I/O Scan Chains* section of this chapter.

Note: `CONFIG_IO` mode is commonly used to configure the I/O pin properties prior to performing boundary scan testing.

Note: The HPS JTAG pins does not support boundary scan tests (BST). To perform boundary scan testing on HPS I/O pins, use the FPGA JTAG.

Functional Description of the Scan Manager

The scan manager serves the following purposes:

- Configuring HPS I/O scan chains
- Communicating with the JTAG TAP controller

Configuring HPS I/O Scan Chains

The HPS I/O pins are configured through a series of scan chains.

I/O pin configuration involves such steps as setting the I/O standard and drive strength for each I/O bank. After a cold reset, all the I/O scan chains in the HPS must be configured prior to being used to communicate with external devices.

Software uses the scan manager to write configuration data to the scan chains. Separate I/O configuration data files for FPGA and HPS are generated by the Quartus® II software when the configuration image for the FPGA portion of the system-on-a-chip (SoC) device is assembled. The HPS configuration data is written to the scan manager by software.

Before configuring a specific I/O bank, the corresponding scan chain must be enabled by writing to the bits in the en register. The scan manager must not be active during this process. Software reads the active bit of the `stat` register to determine the scan manager state.

Alternatively, when the FPGA JTAG TAP controller receives the `CONFIG_IO` JTAG instruction, the control block enters `CONFIG_IO` mode. When the control block is in `CONFIG_IO` mode, the controller can override the scan manager JTAG-AP and configure the HPS I/O pins. The `CONFIG_IO` instruction configures all configurable I/O pins in the SoC device including the FPGA I/O pins and the HPS I/O pins. The FPGA and HPS portions of the device must both be powered on to execute the `CONFIG_IO` instruction. External logic connected to the FPGA JTAG pins sends the `CONFIG_IO` instruction, which provides I/O configuration data for all FPGA and HPS I/O pins. While `CONFIG_IO` mode is active, the HPS is held in cold reset to prevent software from potentially interfering with the I/O configuration.

- **System Manager** on page 5-1
  The HPS I/O pins need to be frozen before configuring them. For more information, refer to the *System Manager* chapter.

Communicating with the JTAG TAP Controller

After the system manager undergoes a cold reset, access to the JTAG TAP controller in the FPGA control block is through the dedicated FPGA JTAG I/O pins. If necessary, you can configure your system to use the scan manager to provide the HPS processor access to the JTAG TAP controller, instead. This feature allows the processor to send JTAG instructions to the FPGA portion of the device.

To connect scan chain 7 between the scan manager and the FPGA JTAG TAP controller, the following features must be enabled:

- The scan chain for the FPGA JTAG TAP controller—To enable scan chain 7, set the `fpgajtag` field of the en register in the scan manager. For more information, refer to *"Scan Manager Address Map and Register Definitions"*.
- The FPGA JTAG logic source select—This source select determines whether the scan manager or the dedicated FPGA JTAG pins are connected to the FPGA JTAG TAP controller in the FPGA portion of the device. On system manager cold reset, the dedicated FPGA JTAG pins are selected. The source select is configured through the `fpgajtagen` bit of the `ctrl` register in the `scanmgrgrp` group of the system manager. The FPGA JTAG pins and scan manager connection to the TAP controller must both be inactive when switching between them. The mechanism to ensure both are inactive is user-defined.

Note: Before connecting or disconnecting the scan chain between the scan manager and the FPGA JTAG TAP controller, ensure that both the FPGA JTAG `TCK` and scan manager `TCK` signals are de-asserted. Altera recommends resetting the FPGA JTAG TAP controller using the scan manager's `nTRST` signal after the scan manager is connected to the controller.

JTAG-AP FIFO Buffer Access and Byte Command Protocol

The JTAG-AP contains FIFO buffers for byte commands and responses. The buffers are accessed through the `fifosinglebyte`, `fifodoublebyte`, `fifotriplebyte`, and `fifoquadbyte` registers. The JTAG-AP stalls processor access to the registers when the buffer does not contain enough data for read access, or when the buffer does not contain enough free space to accept data for write access.

Note: Software should read the `rfifocnt` and `wfifocnt` fields of the `stat` register to determine the buffer status before performing the access to avoid being stalled by the JTAG-AP.

JTAG-AP scan chains 0, 1, 2 and 3 are write-only ports connected to the HPS IOCSRs and JTAG-AP scan chain 7 is a read-write port connected to the FPGA JTAG TAP controller. The processor can send data to scan chains 0-3, and send and receive data from scan chain 7 by accessing the command and response FIFO buffers in the JTAG-AP.

Note: Attempting to access data at invalid or non-aligned offsets can produce unpredictable results that require a reset to recover.

The JTAG commands and `TDI` data must be sent to the JTAG-AP using an encoded byte protocol. Similarly, the `TDO` data received from JTAG-AP is encoded. All commands are 8 bits wide in the byte command protocol.

Table 6-2: JTAG-AP Byte Command Protocol

Bits of the Command Byte								Opcode
7	6	5	4	3	2	1	0	
0	Opcode Payload							`TMS`
1	0	0	Opcode Payload					`TDI_TDO`
1	0	1	X	X	X	X	X	Reserved
1	1	0	X	X	X	X	X	Reserved
1	1	1	X	X	X	X	X	Reserved

Clocks

The scan manager is connected to the `spi_m_clk` clock generated by the clock manager.

The scan manager generates two clocks. One clock routes to the control block of the FPGA portion of the SoC device with a frequency of `spi_m_clk` / 6 and runs at a maximum of 33 MHz. The other clock routes to the HPS I/O scan chains with a frequency of `sp i_m_clk` / 2 and runs at a maximum frequency of 100 MHz.

Note: The `spi_m_clk` can potentially run faster than the scan manager supports so that SPI masters can support 60 Mbps rates. When the SPI master is running faster than what is supported by the scan manager, the scan manager cannot be used and must be held in reset.

Related Information

Clock Manager on page 2-1
For more information, including minimum and maximum clock frequencies, refer to the *Clock Manager* chapter.

Resets

The reset manager provides the `scan_manager_rst_n` reset signal to the scan manager for both cold and warm resets.

Because glitches can happen on the output clocks during a warm reset, the scan manager temporarily stops generation of the JTAG-AP and I/O configuration clocks. This action ensures that a warm reset does not cause output clock glitches.

Before asserting warm reset, the reset manager sends a request to the scan manager. The scan manager stops the output clock generation and acknowledges the reset manager. The reset manager then issues the warm reset. To enable this warm reset handshake, configure the `scanmgrhsen` bit of the reset manager `ctrl` register.

JTAG-AP Register Name Cross Reference Table

To clarify how Altera uses the JTAG-AP, the ARM registers are renamed in the SoC device. The following table cross references the ARM and Altera register names.

Table 6-3: JTAG-AP Register Names

Altera Register Name	ARM Register Name
`stat`	`CSW` (control/status word)
`en`	`PSEL`
`fifosinglebyte`	`BWFIFO1` for writes, `BRFIFO1` for reads
`fifodoublebyte`	`BWFIFO2` for writes, `BRFIFO2` for reads
`fifotriplebyte`	`BWFIFO3` for writes, `BRFIFO3` for reads
`fifoquadbyte`	`BWFIFO4` for writes, `BRFIFO4` for reads

Scan Manager Module Registers Address Map

Registers in the Scan Manager module. These registers are implemented by an ARM JTAG-AP module from the ARM DAP. Some register and field names have been changed to match the usage in the Scan Manager. If modified, the corresponding names from the ARM documentation are provided. Only registers and fields that are relevant to the JTAG-AP use in the Scan Manager are listed.

Base Address: `0xFFF02000`

Scan Manager Module Registers

Register	Offset	Width	Acces s	Reset Value	Description
`stat` on page 6-9	0x0	32	RW	0x0	Control/Status Word Register
`en` on page 6-11	0x4	32	RW	0x0	Scan-Chain Enable Register
`fifosinglebyte` on page 6-12	0x10	32	RW	0x0	FIFO Single Byte Register
`fifodoublebyte` on page 6-13	0x14	32	RW	0x0	FIFO Double Byte Register
`fifotriplebyte` on page 6-13	0x18	32	RW	0x0	FIFO Triple Byte Register
`fifoquadbyte` on page 6-14	0x1C	32	RW	0x0	FIFO Quad Byte Register

stat

Consist of control bit and status information.

Module Instance	Base Address	Register Address

stat Fields

Bit	Name	Description	Access	Reset
31	`active`	Indicates if the Scan-Chain Engine is processing commands from the Command FIFO or not. The Scan-Chain Engine is only guaranteed to be inactive if both the ACTIVE and WFIFOCNT fields are zero. The name of this field in ARM documentation is SERACTV. **Value** **Description** 0x0 The Scan-Chain Engine may or may not be processing commands from the Command FIFO. The Scan-Chain Engine is only guaranteed to be inactive if both this ACTIVE field and the WFIFOCNT fields are both zero. 0x1 The Scan-Chain Engine is processing commands from the Command FIFO.	RO	0x0
30:28	`wfifocnt`	Command FIFO outstanding byte count. Returns the number of command bytes held in the Command FIFO that have yet to be processed by the Scan-Chain Engine.	RO	0x0
26:24	`rfifocnt`	Response FIFO outstanding byte count. Returns the number of bytes of response data available in the Response FIFO.	RO	0x0
3	`ignore`	Ignore this field. Its value is undefined (may be 0 or 1). The name of this field in ARM documentation is PORTCONNECTED.	RO	0x0
1	`trst`	Specifies the value of the nTRST signal driven to the FPGA JTAG only. The FPGA JTAG scan-chain must be enabled via the EN register to drive the value specified in this field. The nTRST signal is driven with the inverted value of this field.The nTRST signal is active low so, when this bit is set to 1, FPGA JTAG is reset. The name of this field in ARM documentation is TRST_OUT. **Value** **Description** 0x0 Don't reset FPGA JTAG. 0x1 Reset FPGA JTAG. Must have the FPGA JTAG scan-chain enabled in the EN register to take effect.	RW	0x0

en

This register is used to enable one of the 5 scan-chains (0-3 and 7). Only one scan-chain must be enabled at a time. A scan-chain is enabled by writing its corresponding enable field. Software must use the System Manager to put the corresponding I/O scan-chain into the frozen state before attempting to send I/O configuration data to the I/O scan-chain. Software must only write to this register when the Scan-Chain Engine is inactive.Writing this field at any other time has unpredictable results. This means that before writing to this field, software must read the STAT register and check that the ACTIVE and WFIFOCNT fields are both zero. The name of this register in ARM documentation is PSEL.

Module Instance	Base Address	Register Address

fifosinglebyte

Writes to the FIFO Single Byte Register write a single byte value to the command FIFO. If the command FIFO is full, the APB write operation is stalled until the command FIFO is not full. Reads from the Single Byte FIFO Register read a single byte value from the command FIFO. If the command FIFO is empty, the APB read operation is stalled until the command FIFO is not empty. See the ARM documentation for a description of the read and write values. The name of this register in ARM documentation is BWFIFO1 for writes and BRFIFO1 for reads.

December 2013	2013.12.30	Minor formatting issues
November 2012	1.2	Added JTAG-AP descriptions.
May 2012	1.1	Added block diagram and system integration, functional description, and address map and register definitions sections.
January 2012	1.0	Initial release.

System Interconnect 7

2014.06.30

cv_54004 Subscribe Send Feedback

The hard processor system (HPS) level 3 (L3) interconnect and level 4 (L4) peripheral buses are implemented with the ARM CoreLink™ Network Interconnect (NIC-301). The NIC-301 provides a foundation for a high-performance HPS interconnect based on the ARM Advanced Microcontroller Bus Architecture (AMBA) Advanced eXtensible Interface (AXI), Advanced High-Performance Bus (AHB™), and Advanced Peripheral Bus (APB™) protocols. The L3 interconnect implements a multilayer, nonblocking architecture that supports multiple simultaneous transactions between masters and slaves, including the Cortex-A9 microprocessor unit (MPU) subsystem. The interconnect provides five independent L4 buses to access control and status registers (CSRs) of peripherals, managers, and memory controllers

Related Information

Additional information is available in the *AMBA Network Interconnect (NIC-301) Technical Reference Manual*, revision r2p3, which you can download from the ARM info center website.

Features of the L3 System Interconnect

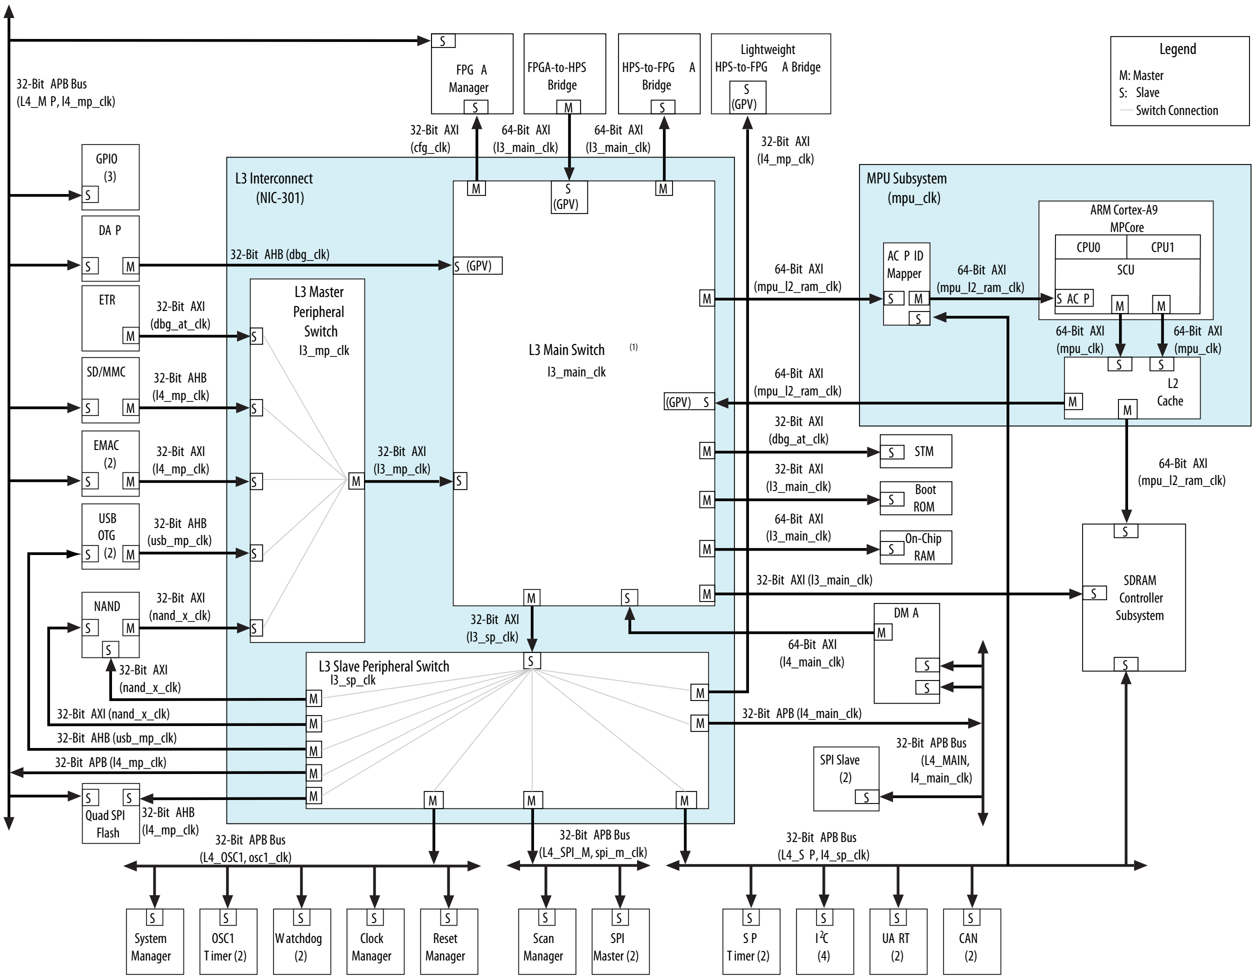
The L3 system interconnect supports high-throughput peripheral devices. The L3 interconnect has the following characteristics:

- Main internal data width of 64 bits
- Programmable master priority with single-cycle arbitration
- Full pipelining to prevent master stalls
- Programmable control for FIFO buffer transaction release
- Security of the following types:
  - Secure
  - Nonsecure
  - Per transaction security
- Five independent L4 buses

Interconnect Block Diagram and System Integration

Interconnect Block Diagram

The following figure shows the L3 interconnect and L4 buses.



Note: Interconnect slaves are available for connection from peripheral masters. Interconnect masters connect to peripheral slaves. This terminology is the reverse of conventional terminology used in Qsys.

Related Information

- Master to Slave Connectivity Matrix on page 7-4
- Main Connectivity Matrix on page 7-3

System Interconnect Architecture

The L3 interconnect is a partially-connected switch fabric. Not all masters can access all slaves.

Internally, the L3 interconnect is partitioned into the following subswitches:

- L3 interconnect
  - Interconnect used to transfer high-throughput 64-bit data
  - Operates at up to half the MPU main clock frequency
  - Provides masters with low-latency connectivity to AXI bridges, on-chip memories, SDRAM, and FPGA manager
- L3 master peripheral switch
  - Used to connect memory-mastering peripherals to the interconnect
  - 32-bit data width
  - Operates at up to half the interconnect clock frequency
- L3 slave peripheral switch
  - Used to provide access to level 3 and 4 slave interfaces for masters of the master peripheral and interconnects
  - 32-bit data width
  - Five independent L4 buses

The L3 master and slave peripheral switches are fully-connected crossbars. The L3 interconnect is a partially-connected crossbar. The following table shows the connectivity matrix of all the master and slave interfaces of the L3 interconnect.

Main Connectivity Matrix

The L3 master and slave peripheral switches are fully-connected crossbars. The L3 interconnect is a partially-connected crossbar. The following table shows the connectivity matrix of all the master and slave interfaces of the L3 interconnect.

Address Remapping

The interconnect supports address remapping through the `remap` register in the `l3regs` group. Remapping allows software to control which memory device (SDRAM, on-chip RAM, or boot ROM) is accessible at address 0x0 and the accessibility of the HPS-to-FPGA and lightweight HPS-to-FPGA bridges. The `remap` register is one of the NIC-301 Global Programmers View (GPV) registers. The following L3 masters can manipulate `remap`, because it maps into their address space:

- MPU
- FPGA-to-HPS bridge
- DAP

The remapping bits in the `remap` register are not mutually exclusive. The lowest order remap bit has higher priority when multiple slaves are remapped to the same address. Each bit allows different combinations of address maps to be formed. There is only one remapping register available in the GPV, so modifying the `remap` register affects all memory maps of all the masters of the interconnect.

The effects of the remap bits can be categorized in the following groups:

- MPU master interface
    - L2 cache master 0 interface
- Non-MPU master interfaces
    - DMA master interface
    - Master peripheral interfaces
    - Debug Access Port (DAP) master interface
    - FPGA-to-HPS bridge master interface

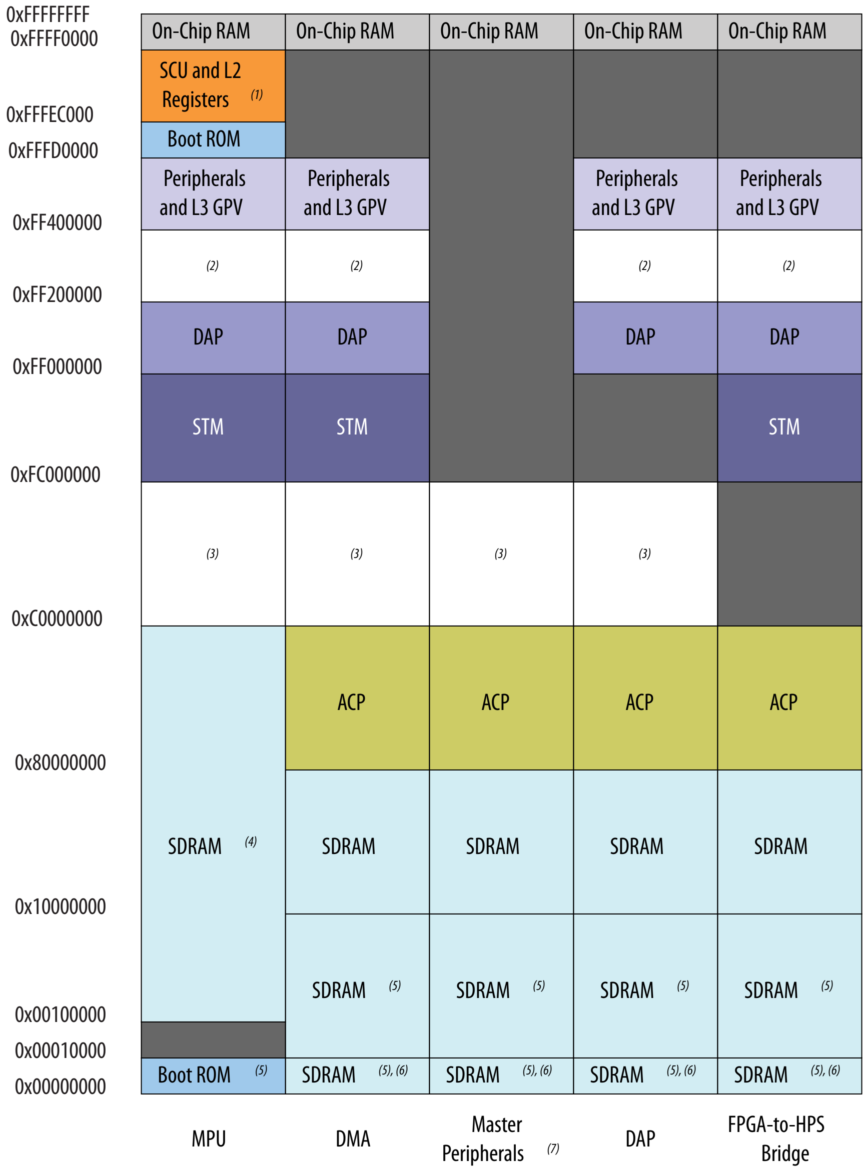
Available Address Maps

Figure 7-2: Address Maps for Interconnect Masters

The following figure shows the default interconnect address maps for all masters. The figure is not to scale.



Notes on Address Maps

(1) Transactions on these addresses pass through the L2 interconnect.

(2) This region can be configured to access slaves on the lightweight HPS-to-FPGA bridge, by using the `remap` register.

(3) This region can be configured to access slaves on the HPS-to-FPGA bridge, by using the `remap` register.

(4) The MPU accesses SDRAM through a dedicated port.

[5] This region can be configured to access the ACP, by using the remap register.

[6] This region can be configured to access on-chip RAM, by using the remap register.

[7] The following peripherals can master the interconnect:

- Ethernet MACs
- USB-2 OTG controllers
- NAND controllers
- ETR
- SD/MMC controller

For the MPU L3 master, either the boot ROM or on-chip RAM maps to address 0x0 and obscures the lowest 64 KB of SDRAM. The address space from 0x00010000 to 0x00100000 is not accessible because the MPU L2 filter registers only have a granularity of 1 MB. After booting completes, the MPU can change address filtering to use the lowest 1 MB of SDRAM.

For non-MPU masters, either the on-chip RAM or the SDRAM maps to address 0x0. When mapped to address 0x0, the on-chip RAM obscures the lowest 64 KB of SDRAM for non-MPU masters.

Related Information

remap on page 7-24
Description of the remap register

Memory Map Remap Bits

Bit Name	Bit Offset	Description
mpuzero	0	When set to 0, the boot ROM maps to address 0x0 for the MPU L3 master. When set to 1, the on-chip RAM maps to address 0x0 for the MPU L3 master. This bit has no effect on non-MPU masters. Note that regardless of this setting, the boot ROM also always maps to address 0xffff0000 and the on-chip RAM also always maps to address 0xfffd0000 for the MPU L3 master.
nonmpuzero	1	When set to 0, the SDRAM maps to address 0x0 for the non-MPU L3 masters. When set to 1, the on-chip RAM maps to address 0x0 for the non-MPU masters. This bit has no effect on the MPU L3 master. Note that regardless of this setting, the on-chip RAM also always maps to address 0xfffd0000 for the non-MPU L3 masters.
Reserved	2	Must always be set to 0.
hps2fpga	3	When set to 1, the HPS-to-FPGA bridge slave port is visible to the L3 masters. When set to 0, accesses to the associated address range return an AXI decode error to the master.
lwhp2fpga	4	When set to 1, the lightweight HPS-to-FPGA bridge slave port is visible to the L3 masters. When set to 0, accesses to the associated address range return an AXI decode error to the master.

Bit Name	Bit Offset	Description
Reserved	31:5	Must always be set to 0.

Note: L2 filter registers in the MPU subsystem, not the interconnect, allow the SDRAM to be remapped to address `0x0` for the MPU.

Master Caching and Buffering Overrides

Some of the peripheral masters connected to the interconnect do not have the ability to drive the caching and buffering signals of their interfaces. The system manager provides registers so that you can enable cacheable and bufferable transactions for these masters. The system manager drives the caching and buffering signals of the following masters:

Master Peripheral	System Manager Register Group	Register
EMAC0 and EMAC1	`emacgrp`	`l3master`
USB OTG 0 and USB OTG 1	`usbgrp`	`l3master`
NAND flash	`nandgrp`	`l3master`
SD/MMC	`sdmmcgrp`	`l3master`

At reset time, the system manager drives the cache and buffering signals for these masters low. In other words, the masters listed do not support cacheable or bufferable accesses until you enable them after reset. There is no synchronization between the system manager and the interconnect, so avoid changing these settings when any of the masters are active.

Related Information

System Manager on page 5-1

For more information about enabling or disabling these features, refer to the *System Manager* chapter.

Security

Slave Security

The interconnect enforces security through the slave settings. The slave settings are controlled by the address region control registers accessible through the GPV registers. Each L3 and L4 slave has its own security check and programmable security settings. After reset, every slave of the interconnect is set to a secure state (referred to as boot secure). The only accesses allowed to secure slaves are by secure masters.

The GPV can only be accessed by secure masters. The security state of the interconnect is not accessible through the GPV as the security registers are write-only. Any nonsecure accesses to the GPV receive a `DECERR` response, and no register access is provided. Updates to the security settings through the GPV do not take effect until all transactions to the affected slave have completed.

Master Security

Masters of the interconnect are either secure, nonsecure, or the security is set on a per transaction basis. The DAP is capable of performing only secure accesses. The L2 cache master 0, FPGA-to-HPS-bridge, and DMA perform secure and nonsecure accesses on a per transaction basis. All other interconnect masters perform nonsecure accesses.

Accesses to secure slaves by unsecure masters result in a response of DECERR and the transaction does not reach the slave.

Related Information

Interconnect Master Properties on page 7-10

Arbitration

At the entry point to the interconnect, all transactions are allocated a local quality of service (QoS). QoS specifies the transaction's arbitration priority. The interconnect allows transactions with a higher QoS to use a greater share of interconnect bandwidth. The transaction arbitration throughout the interconnect uses this QoS value. The QoS controls for each master connected to the interconnect are separated into read and write QoS priority values.

At any arbitration node, a fixed priority exists for transactions with different QoS values. The highest QoS value has the highest priority. If there are coincident transactions at an arbitration node with the same QoS value that require arbitration, then the interconnect uses a least recently used (LRU) algorithm.

You can programmatically configure the QoS value for each master through the appropriate `write_qos` register.

Related Information

L3 (NIC-301) GPV Registers Address Map on page 7-17
Information about the GPV `write_qos` registers

Cyclic Dependency Avoidance Schemes

The AXI protocol permits re-ordering of transactions. As a result, when routing concurrent multiple transactions from a single point of divergence to multiple slaves, the interconnect might need to enforce rules to prevent deadlock.

Each master of the interconnect is configured with one of three possible cyclic dependency avoidance schemes (CDAS). The same CDAS scheme is configured for both read and write transactions, but they operate independently.

Single Slave on page 7-9

Single Slave Per ID on page 7-10

Single Active Slave on page 7-10

Related Information

Interconnect Master Properties on page 7-10
Contains descriptions of the CDAS implementation for the masters.

Single Slave

Single slave (SS) ensures the following conditions at a slave interface of a switch:

- All outstanding read transactions are to a single end destination.
- All outstanding write transactions are to a single end destination.

If a master issues another transaction to a different destination than the current destination for that transaction type (read or write), the network stalls the transactions until all the outstanding transactions of that type have completed.

Single Slave Per ID

Single slave per ID (SSPID) ensures the following conditions at a slave interface of a switch:

- All outstanding read transactions with the same ID go the same destination.
- All outstanding write transactions with the same ID go the same destination.

When a master issues a transaction, the following situations can occur:

- If the transaction has an ID that does not match any outstanding transactions, it passes the CDAS.
- If the transaction has an ID that matches the ID of an outstanding transaction, and the destinations also match, it passes the CDAS.
- If the transaction has an ID that matches the ID of an outstanding transaction, and the destinations do not match, the transaction fails the CDAS check and stalls.

Single Active Slave

Single active slave (SAS) is the same as the SSPID scheme, with an added check for write transactions. SAS ensures that a master cannot issue a new write address until all of the data from the previous write transaction has been sent.

Interconnect Master Properties

The system interconnect connects to various slave interfaces through the L3 interconnect and L3 slave peripheral switch.

Table 7-1: Interconnect Master Interfaces

TrustZone security:

- Secure: All transactions are marked TrustZone secure
- Nonsecure: All transactions are marked TrustZone non-secure
- Per transaction: Transactions can be marked TrustZone secure or TrustZone non-secure, depending on the state of the interconnect master.

Issuance is based on the number of read, write, and total transactions.

The FIFO buffer depth for AXI is based on the AW, AR, R, W, and B channels. For AHB and APB, the depth is based on W, A, and D channels.

Master	Interface Width	Clock	Switch	TrustZone Security	GPV Access	CDAS	Issuance	FIFO Buffer Depth	Type
L2 cache M0	64	`mpu_l2_ram_clk`	L3 interconnect	Per Transaction	Yes	SSPID	7, 12, 19	2, 2, 2, 2, 2	AXI
FPGA-to-HPS bridge	64	`l3_main_clk`	L3 interconnect	Per Transaction	Yes	SAS	16, 16, 32	2, 2, 6, 6, 2	AXI

Upsizing Data Width Function

The upsizing function combines narrow transactions into wider transactions to increase the overall system bandwidth. Upsizing only packs data for read or write transactions that are cacheable. If the interconnect splits input-exclusive transactions into more than one output bus transaction, it removes the exclusive information from the multiple transactions it creates.

The upsizing function can expand the data width by the following ratios:

- 1:2
- 1:4

If multiple responses from created transactions are combined into one response, then the following order of priority applies:

- `DECERR` is the highest priority
- `SLVERR` is the next highest priority
- `OKAY` is the lowest priority.

Related Information

http://infocenter.arm.com/

Additional information is available in the *AMBA Network Interconnect (NIC-301) Technical Reference Manual*, revision r2p3, which you can download from the ARM Infocenter website.

Incrementing Bursts

The interconnect converts all input `INCR` bursts that complete within a single output data width to an `INCR1` burst of the minimum `SIZE` possible, and packs all `INCR` bursts into `INCR` bursts of the optimal size possible for maximum data throughout.

Wrapping Bursts

All `WRAP` bursts are either passed through unconverted as `WRAP` bursts, or converted to one or two `INCR` bursts of the output bus. The interconnect converts input `WRAP` bursts that have a total payload less than the output data width to a single `INCR` burst.

[9] Acceptance is based on the number of read, write, and total transactions.

[10] The FIFO buffer depth for AXI is based on the AW, AR, R, W, and B channels. For AHB and APB, the depth is based on W, A, and D channels.

[10] The FIFO buffer depth for AXI is based on the AW, AR, R, W, and B channels. For AHB and APB, the depth is based on W, A, and D channels.

Fixed Bursts

All FIXED bursts pass through unconverted.

Bypass Merge

Bypass merge is accessible through the GPV registers and is only accessible to secure masters. If the programmable bit bypass_merge is enabled, the interconnect does not alter any transactions that could pass through legally without alteration.

Downsizing Data Width Function

The downsizing function reduces the data width of a transaction to match the optimal data width at the destination. Downsizing does not merge multiple-transaction data narrower than the destination bus if the transactions are marked as noncacheable.

The downsizing function reduces the data width by the following ratios:

- 2:1
- 4:1

Incrementing Bursts

The interconnect converts INCR bursts that fall within the maximum payload size of the output data bus to a single INCR burst. It converts INCR bursts that are greater than the maximum payload size of the output data bus to multiple INCR bursts.

INCR bursts with a size that matches the output data width pass through unconverted.

The interconnect packs INCR bursts with a SIZE smaller than the output data width to match the output width whenever possible, using the upsizing function.

Related Information

Upsizing Data Width Function on page 7-14

For more information about AXI terms such as DECERR, WRAP, and INCR, refer to the *AMBA AXI Protocol Specification v1.0*, which you can download from the ARM website.

Wrapping Bursts

The interconnect always converts WRAP bursts to WRAP bursts of twice the length, up to the output data width maximum size of WRAP16, and treats the WRAP burst as two INCR bursts that can each be converted into one or more INCR bursts.

Fixed Bursts

The interconnect converts FIXED bursts to one or more INCR1 or INCRn bursts depending on the downsize ratio.

Bypass Merge

Bypass merge is accessible through the GPV registers and is only accessible to secure masters. If the programmable bit bypass_merge in the fn_mod2 register is enabled, the interconnect does not perform any packing of beats to match the optimal size for maximum throughput, up to the output data width size.

If an exclusive transaction is split into multiple transactions at the output of the downsizing function, the exclusive flag is removed and the master never receives an EXOKAY response. Response priority is the same as for the upsizing function.

Related Information

- **fn_mod2** on page 7-80
- **Upsizing Data Width Function** on page 7-14
  For more information about AXI terms such as DECERR, WRAP, and INCR, refer to the *AMBA AXI Protocol Specification v1.0*, which you can download from the ARM website.

Lock Support

Lock is not supported by the interconnect. For atomic accesses, masters can perform exclusive accesses when sharing data located in the HPS SDRAM.

Related Information

Functional Description—HPS Memory Controller on page 11-1
For more information about exclusive access support, refer to the *SDRAM Controller Subsystem* chapter.

FIFO Buffers and Clocks

The interconnect contains FIFO buffers in the majority of the interfaces exposed to the HPS master and slaves, as well as between the subswitches. These FIFO buffers also provide clock domain crossing for masters and slaves that operate at a different clock frequency than the switch they connect to.

Data Release Mechanism

For interconnect ports with data FIFO buffers whose depth is greater than zero, you can set a write tidemark function, `wr_tidemark`. This tidemark level stalls the release of the transaction until one of the following situations occurs:

- The interconnect receives the `WLAST` beat of a burst.
- The write data FIFO buffer becomes full.
- The number of occupied slots in the write data FIFO buffer exceeds the write tidemark.

Related Information

- **Interconnect Master Properties** on page 7-10
  Indicates which master interfaces have data FIFO buffers with a nonzero depth
- **Interconnect Slave Properties** on page 7-11
  Indicates which slave interfaces have data FIFO buffers with a nonzero depth

Resets

The interconnect has one reset signal. The reset manager drives this signal to the interconnect on a cold or warm reset. On reset, the boot ROM is mapped to address 0x0.

Related Information

Reset Manager on page 3-1

Interconnect Address Map and Register Definitions

This section lists the interconnect register address map and describes the registers.

Note: Interconnect slaves are available for connection from peripheral masters. Interconnect masters connect to peripheral slaves. This terminology is the reverse of conventional terminology used in Qsys.

remap

The L3 interconnect has separate address maps for the various L3 Masters. Generally, the addresses are the same for most masters. However, the sparse interconnect of the L3 switch causes some masters to have holes in their memory maps. The remap bits are not mutually exclusive. Each bit can be set independently and in combinations. Priority for the bits is determined by the bit offset: lower offset bits take precedence over higher offset bits.

Module Instance	Base Address	Register Address
l3regs	0xFF800000	0xFF800000

Offset: 0x0

Access: WO

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

remap Fields

Bit	Name	Description	Access	Reset
4	lwhps2fpga	Controls whether the Lightweight HPS2FPGA AXI Bridge is visible to L3 masters or not. **Value** **Description** 0x0 The LWHPS2FPGA AXI Bridge is not visible to L3 masters. Accesses to the associated address range return an AXI decode error to the master. 0x1 The LWHPS2FPGA AXI Bridge is visible to L3 masters.	WO	0x0
3	hps2fpga	Controls whether the HPS2FPGA AXI Bridge is visible to L3 masters or not. **Value** **Description** 0x0 The HPS2FPGA AXI Bridge is not visible to L3 masters. Accesses to the associated address range return an AXI decode error to the master. 0x1 The HPS2FPGA AXI Bridge is visible to L3 masters.	WO	0x0

Bit	Name	Description	Access	Reset
1	`nonmpuzero`	Controls the mapping of address 0x0 for L3 masters other than the MPU. Determines whether address 0x0 for these masters is mapped to the SDRAM or on-chip RAM. Only affects the following masters: DMA controllers (standalone and those built in to peripherals), FPGA-to-HPS Bridge, and DAP. **Value** **Description** 0x0 Maps the SDRAM to address 0x0 for the non-MPU L3 masters. 0x1 Maps the On-chip RAM to address 0x0 for the non-MPU L3 masters. Note that the On-chip RAM is also always mapped to address 0xffff_0000 for the non-MPU L3 masters independent of this field's value.	WO	0x0
0	`mpuzero`	Controls whether address 0x0 for the MPU L3 master is mapped to the Boot ROM or On-chip RAM. This field only has an effect on the MPU L3 master. **Value** **Description** 0x0 Maps the Boot ROM to address 0x0 for the MPU L3 master. Note that the Boot ROM is also always mapped to address 0xfffd_0000 for the MPU L3 master independent of this field's value. 0x1 Maps the On-chip RAM to address 0x0 for the MPU L3 master. Note that the On-chip RAM is also always mapped to address 0xffff_0000 for the MPU L3 master independent of this field's value.	WO	0x0

Document Revision History

Table 7-3: Document Revision History

Date	Version	Changes
June 2014	2014.06.30	• Corrected master interconnect security properties for: • Ethernet MAC • ETR • Added address map and register descriptions
February 2014	2014.02.28	Maintenance release
December 2013	2013.12.30	Maintenance release
November 2012	1.2	Minor updates.
June 2012	1.1	• Added interconnect connectivity matrix. • Rearranged functional description sections. • Simplified address remapping section. • Added address map and register definitions section.
January 2012	1.0	Initial release.

HPS-FPGA Bridges

8

2014.07.31

cv_54005 Subscribe Send Feedback

This chapter describes the bridges in the hard processor system (HPS) used to communicate data between the FPGA fabric and HPS logic. The bridges use the Advanced Microcontroller Bus Architecture (AMBA) Advanced eXtensible Interface (AXI) protocol, and are based on the AMBA Network Interconnect (NIC-301).

The HPS contains the following HPS-FPGA bridges:

- FPGA-to-HPS Bridge
- HPS-to-FPGA Bridge
- Lightweight HPS-to-FPGA Bridge

- **Lightweight HPS-to-FPGA Bridge Clocks and Resets** on page 8-48
- **http://infocenter.arm.com/**
  Additional information is available in the AMBA AXI Protocol Specification v1.0 and the AMBA Network Interconnect (NIC-301) Technical Reference Manual, which you can download from the ARM Infocenter website.

Features of the HPS-FPGA Bridges

The HPS-FPGA bridges allow masters in the FPGA fabric to communicate with slaves in the HPS logic and vice versa. For example, you can instantiate additional memories or peripherals in the FPGA fabric, and master interfaces belonging to components in the HPS logic can access them. You can also instantiate components such as a Nios® II processor in the FPGA fabric and their master interfaces can access memories or peripherals in the HPS logic.

Table 8-1: HPS-FPGA Bridge Features

Feature	FPGA-to-HPS Bridge	HPS-to-FPGA Bridge	Lightweight HPS-to-FPGA Bridge
Supports the AMBA AXI3 interface protocol	Y	Y	Y
Implements clock crossing and manages the transfer of data across the clock domains in the HPS logic and the FPGA fabric	Y	Y	Y
Performs data width conversion between the HPS logic and the FPGA fabric	Y	Y	Y
Allows configuration of FPGA interface widths at instantiation time	Y	Y	N

Each bridge consists of a master-slave pair with one interface exposed to the FPGA fabric and the other exposed to the HPS logic. The FPGA-to-HPS bridge exposes an AXI slave interface that you can connect to AXI master or Avalon-MM interfaces in the FPGA fabric. The HPS-to-FPGA and lightweight HPS-to-FPGA bridges expose an AXI master interface that you can connect to AXI or Avalon-MM slave interfaces in the FPGA fabric.

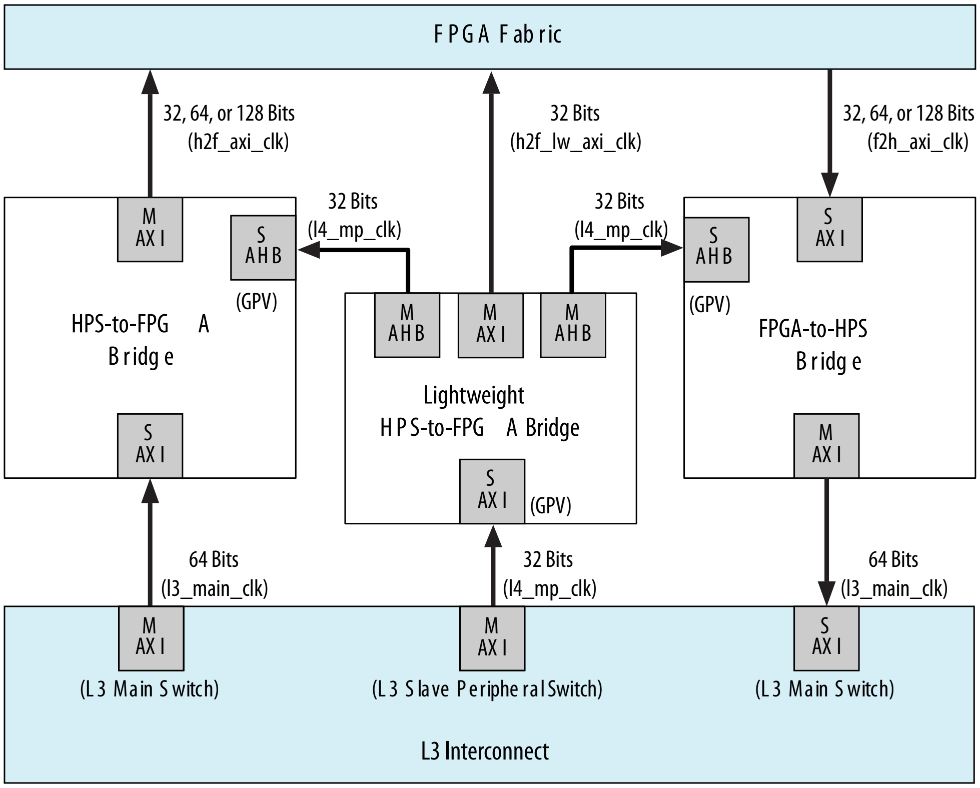
Information about configuring the AXI bridges

HPS-FPGA Bridges Block Diagram and System Integration

Figure 8-1: HPS-FPGA Bridge Connectivity

The following figure shows the HPS-FPGA bridges in the context of the FPGA fabric and the L3 interconnect to the HPS. Each master (M) and slave (S) interface is shown with its data width(s). The clock domain for each interconnect is shown in parentheses.



The HPS-to-FPGA bridge is mastered by the level 3 (L3) main switch and the lightweight HPS-to-FPGA bridge is mastered by the L3 slave peripheral switch.

The FPGA-to-HPS bridge masters the L3 main switch, allowing any master implemented in the FPGA fabric to access most slaves in the HPS. For example, the FPGA-to-HPS bridge can access the accelerator coherency port (ACP) of the Cortex-A9 MPU subsystem to perform cache-coherent accesses to the SDRAM subsystem.

All three bridges contain global programmers view (GPV) registers. The GPV registers control the behavior of the bridge. Access to the GPV registers of all three bridges is provided through the lightweight HPS-to-FPGA bridge.

  Detailed information about connectivity, such as which masters have access to each bridge

Functional Description of the HPS-FPGA Bridges

The Global Programmers View

The HPS-to-FPGA bridge includes a set of registers called the GPV. The GPV provides settings to control the bridge properties and behavior. Access to the GPV registers of all three bridges is provided through the lightweight HPS-to-FPGA bridge.

The GPV registers can only be accessed by secure masters in the HPS or the FPGA fabric.

FPGA-to-HPS Bridge

The FPGA-to-HPS bridge provides access to the peripherals and memory in the HPS. This access is available to any master implemented in the FPGA fabric. You can configure the bridge slave, which is exposed to the FPGA fabric, to support 32-, 64-, or 128-bit data. The master interface of the bridge, connected to the L3 interconnect, has a data width of 64 bits.

Table 8-2: FPGA-to-HPS Bridge Properties

The following table lists the properties of the FPGA-to-HPS bridge, including the configurable slave interface exposed to the FPGA fabric.

Bridge Property	FPGA Slave Interface	L3 Master Interface
Data width[11]	32, 64, or 128 bits	64 bits
Clock domain	`f2h_axi_clk`	`l3_main_clk`
Byte address width	32 bits	32 bits
ID width	8 bits	8 bits
Read acceptance	16 transactions	16 transactions
Write acceptance	16 transactions	16 transactions
Total acceptance	32 transactions	32 transactions

The FPGA-to-HPS bridge address map contains a GPV. The GPV registers provide settings that adjust the bridge slave properties when the FPGA slave interface is configured to be 32 or 128 bits wide. The slave issuing capability can be adjusted, through the `fn_mod` register, to allow one or multiple transactions to be outstanding in the HPS. The slave bypass merge feature can also be enabled, through the `bypass_merge` bit in the `fn_mod2` register. This feature ensures that the upsizing and downsizing logic does not alter any transactions when the FPGA slave interface is configured to be 32 or 128 bits wide.

Note: It is critical to provide the correct `l4_mp_clk` clock to support access to the GPV, as described in "GPV Clocks".

[11] The bridge slave data width is user-configurable at the time you instantiate the HPS component in your system.

FPGA-to-HPS Access to ACP

When the error correction code (ECC) option is enabled in the level 2 (L2) cache controller, all accesses from the FPGA-to-HPS bridge to the ACP must be 64 bits wide and aligned on 8-byte boundaries after up- or downsizing takes place.

Table 8-3: FPGA Master and FPGA-to-HPS Bridge Configurations

The following table lists some possible master and FPGA-to-HPS bridge slave configurations that support accesses to the L2 cache with ECC enabled.

Soft Logic Master Width	Soft Logic Master Alignment	Soft Logic Master Burst Size (Width)	Soft Logic Master Burst Length	FPGA-to-HPS Bridge Slave Width
32 bits	8 bytes	4 bytes	2, 4, 6, 8, 10, 12, 14, or 16 beats	32 bits
64 bits	8 bytes	8 bytes	1 to 16 beats	32 bits
128 bits	8 or 16 bytes	8 or 16 bytes	1 to 16 beats	32 bits
32 bits	8 bytes	4 bytes	2, 4, 6, 8, 10, 12, 14, or 16 beats	64 bits
64 bits	8 bytes	8 bytes	1 to 16 beats	64 bits
128 bits	8 or 16 bytes	8 or 16 bytes	1 to 16 beats	64 bits
32 bits	8 bytes	4 bytes	2, 4, 6, 8, 10, 12, 14, or 16 beats	128 bits
64 bits	8 bytes	8 bytes	1 to 16 beats	128 bits
128 bits	8 or 16 bytes	8 or 16 bytes	1 to 16 beats	128 bits

FPGA-to-HPS Bridge Slave Signals

The FPGA-to-HPS bridge slave address channels support user-sideband signals, routed to the ACP in the MPU subsystem. All the signals have a fixed width except the data and write strobes for the read and write data channels. The variable width signals depend on the data width setting of the bridge.

The following tables list all the signals exposed by the FPGA-to-HPS slave interface to the FPGA fabric.

Table 8-4: FPGA-to-HPS Bridge Slave Write Address Channel Signals

Signal	Width	Direction	Description
AWID	8 bits	Input	Write address ID
AWADDR	32 bits	Input	Write address
AWLEN	4 bits	Input	Burst length
AWSIZE	3 bits	Input	Burst size
AWBURST	2 bits	Input	Burst type
AWLOCK	2 bits	Input	Lock type—Valid values are 00 (normal access) and 01 (exclusive access)
AWCACHE	4 bits	Input	Cache policy type
AWPROT	3 bits	Input	Protection type
AWVALID	1 bit	Input	Write address channel valid
AWREADY	1 bit	Output	Write address channel ready
AWUSER	5 bits	Input	User sideband signals

Table 8-5: FPGA-to-HPS Bridge Slave Write Data Channel Signals

Signal	Width	Direction	Description
WID	8 bits	Input	Write ID
WDATA	32, 64, or 128 bits	Input	Write data
WSTRB	4, 8, or 16 bits	Input	Write data strobes
WLAST	1 bit	Input	Write last data identifier
WVALID	1 bit	Input	Write data channel valid
WREADY	1 bit	Output	Write data channel ready

Table 8-6: FPGA-to-HPS Bridge Slave Write Response Channel Signals

Signal	Width	Direction	Description
BID	8 bits	Output	Write response ID

Signal	Width	Direction	Description
BRESP	2 bits	Output	Write response
BVALID	1 bit	Output	Write response channel valid
BREADY	1 bit	Input	Write response channel ready

Table 8-7: FPGA-to-HPS Bridge Slave Read Address Channel Signals

Signal	Width	Direction	Description
ARID	8 bits	Input	Read address ID
ARADDR	32 bits	Input	Read address
ARLEN	4 bits	Input	Burst length
ARSIZE	3 bits	Input	Burst size
ARBURST	2 bits	Input	Burst type
ARLOCK	2 bits	Input	Lock type—Valid values are 00 (normal access) and 01 (exclusive access)
ARCACHE	4 bits	Input	Cache policy type
ARPROT	3 bits	Input	Protection type
ARVALID	1 bit	Input	Read address channel valid
ARREADY	1 bit	Output	Read address channel ready
ARUSER	5 bits	Input	Read user sideband signals

Table 8-8: FPGA-to-HPS Bridge Slave Read Data Channel Signals

Signal	Width	Direction	Description
RID	8 bits	Output	Read ID
RDATA	32, 64, or 128 bits	Output	Read data
RRESP	2 bits	Output	Read response
RLAST	1 bit	Output	Read last data identifier
RVALID	1 bit	Output	Read data channel valid

Signal	Width	Direction	Description
RREADY	1 bit	Input	Read data channel ready

HPS-to-FPGA Bridge

The HPS-to-FPGA bridge provides a configurable-width, high-performance master interface to the FPGA fabric. The bridge provides most masters in the HPS with access to logic, peripherals, and memory implemented in the FPGA. The effective size of the address space is 0x3FFF0000, or 1 gigabyte (GB) minus 64 megabytes (MB). The address space size is less than 1 GB because 64 MB is occupied by peripherals, lightweight HPS-to-FPGA bridge, on-chip RAM, and boot ROM in the HPS. You can configure the bridge master exposed to the FPGA fabric for 32-, 64-, or 128-bit data. The amount of address space exposed to the MPU subsystem can also be reduced through the L2 cache address filtering mechanism.

The slave interface of the bridge in the HPS logic has a data width of 64 bits. The bridge provides width adaptation and clock crossing logic that allows the logic in the FPGA to operate in any clock domain, asynchronous from the HPS.

Note: The HPS-to-FPGA bridge is accessed if the MPU boots from the FPGA. Before the MPU boots from the FPGA, the FPGA portion of the SoC device must be configured, and the HPS-to-FPGA bridge must be remapped into addressable space.

Table 8-9: HPS-to-FPGA Bridge Properties

The following table lists the properties of the HPS-to-FPGA bridge, including the configurable master interface exposed to the FPGA fabric.

Bridge Property	L3 Slave Interface	FPGA Master Interface
Data width [12]	64 bits	32, 64, or 128 bits
Clock domain	`l3_main_clk`	`h2f_axi_clk`
Byte address width	32 bits	30 bits
ID width	12 bits	12 bits

[12] The bridge master data width is user-configurable at the time you instantiate the HPS component in your system.

Bridge Property	L3 Slave Interface	FPGA Master Interface
Read acceptance	16 transactions	16 transactions
Write acceptance	16 transactions	16 transactions
Total acceptance	32 transactions	32 transactions

The HPS-to-FPGA bridge's GPV, described in "The Global Programmers View", provides settings to adjust the bridge master properties. The master issuing capability can be adjusted, through the `fn_mod` register, to allow one or multiple transactions to be outstanding in the FPGA fabric. The master bypass merge feature can also be enabled, through the `bypass_merge` bit in the `fn_mod2` register. This feature ensures that the upsizing and downsizing logic does not alter any transactions when the FPGA master interface is configured to be 32 or 128 bits wide.

Note: It is critical to provide the correct `l4_mp_clk` clock to support access to the GPV, as described in "GPV Clocks".

HPS-to-FPGA Bridge Master Signals

All the HPS-to-FPGA bridge master signals have a fixed width except the data and write strobes for the read and write data channels. The variable-width signals depend on the data width setting of the bridge interface exposed to the FPGA logic.

The following tables list all the signals exposed by the HPS-to-FPGA master interface to the FPGA fabric.

Table 8-10: HPS-to-FPGA Bridge Master Write Address Channel Signals

Signal	Width	Direction	Description
`AWID`	12 bits	Output	Write address ID
`AWADDR`	30 bits	Output	Write address
`AWLEN`	4 bits	Output	Burst length
`AWSIZE`	3 bits	Output	Burst size
`AWBURST`	2 bits	Output	Burst type

Lightweight HPS-to-FPGA Bridge

The lightweight HPS-to-FPGA bridge provides a lower-performance interface to the FPGA fabric. This interface is useful for accessing the control and status registers of soft peripherals. The bridge provides a 2 MB address space and access to logic, peripherals, and memory implemented in the FPGA fabric. The MPU subsystem, direct memory access (DMA) controller, and debug access port (DAP) can use the lightweight HPS-to-FPGA bridge to access the FPGA fabric or GPV. Master interfaces in the FPGA fabric can also use the lightweight HPS-to-FPGA bridge to access the GPV registers in all three bridges.

The bridge master exposed to the FPGA fabric has a fixed data width of 32 bits. The slave interface of the bridge in the HPS logic has a fixed data width of 32 bits.

Use the lightweight HPS-to-FPGA bridge as a secondary, lower-performance master interface to the FPGA fabric. With a fixed width and a smaller address space, the lightweight bridge is useful for low-bandwidth traffic, such as memory-mapped register accesses to FPGA peripherals. This approach diverts traffic from the high-performance HPS-to-FPGA bridge, and can improve both CSR access latency and overall system performance.

Table 8-15: Lightweight HPS-to-FPGA Bridge Properties

This table lists the properties of the lightweight HPS-to-FPGA bridge, including the master interface exposed to the FPGA fabric.

Bridge Property	L3 Slave Interface	FPGA Master Interface
Data width	32 bits	32 bits
Clock domain	`l4_mp_clk`	`h2f_lw_axi_clk`
Byte address width	32 bits	21 bits
ID width	12 bits	12 bits
Read acceptance	16 transactions	16 transactions
Write acceptance	16 transactions	16 transactions

Bridge Property	L3 Slave Interface	FPGA Master Interface
Total acceptance	32 transactions	32 transactions

The lightweight HPS-to-FPGA bridge has three master interfaces. The master interface connected to the FPGA fabric provides a lightweight interface from the HPS to custom logic in the FPGA fabric. The two other master interfaces, connected to the HPS-to-FPGA and FPGA-to-HPS bridges, allow you to access the GPV registers for each bridge.

The lightweight HPS-to-FPGA bridge also has a set of registers GPV to control the behavior of its four interfaces (one slave and three masters).

The GPV allows you to set the bridge's issuing capabilities to support single or multiple transactions. The GPV also lets you set a write tidemark through the `wr_tidemark` register, to control how much data is buffered in the bridge before data is written to slaves in the FPGA fabric.

Note: It is critical to provide correct clock settings for the lightweight HPS-to-FPGA bridge, even if your design does not use this bridge. The `l4_mp_clk` clock is required for GPV access on the HPS-to-FPGA and FPGA-to-HPS bridges.

Lightweight HPS-to-FPGA Bridge Master Signals

All the lightweight HPS-to-FPGA bridge master signals have a fixed width.

The following tables list all the signals exposed by the lightweight HPS-to-FPGA master interface to the FPGA fabric.

Table 8-16: Lightweight HPS-to-FPGA Bridge Master Write Address Channel Signals

Signal	Width	Direction	Description
AWID	12 bits	Output	Write address ID
AWADDR	21 bits	Output	Write address
AWLEN	4 bits	Output	Burst length
AWSIZE	3 bits	Output	Burst size
AWBURST	2 bits	Output	Burst type

Signal	Width	Direction	Description
AWLOCK	2 bits	Output	Lock type—Valid values are 00 (normal access) and 01 (exclusive access)
AWCACHE	4 bits	Output	Cache policy type
AWPROT	3 bits	Output	Protection type
AWVALID	1 bit	Output	Write address channel valid
AWREADY	1 bit	Input	Write address channel ready

Table 8-17: Lightweight HPS-to-FPGA Bridge Master Write Data Channel Signals

Signal	Width	Direction	Description
WID	12 bits	Output	Write ID
WDATA	32 bits	Output	Write data
WSTRB	4 bits	Output	Write data strobes
WLAST	1 bit	Output	Write last data identifier
WVALID	1 bit	Output	Write data channel valid
WREADY	1 bit	Input	Write data channel ready

Table 8-18: Lightweight HPS-to-FPGA Bridge Master Write Response Channel Signals

Signal	Width	Direction	Description
BID	12 bits	Input	Write response ID
BRESP	2 bits	Input	Write response
BVALID	1 bit	Input	Write response channel valid
BREADY	1 bit	Output	Write response channel ready

Table 8-19: Lightweight HPS-to-FPGA Bridge Master Read Address Channel Signals

Signal	Width	Direction	Description
ARID	12 bits	Output	Read address ID
ARADDR	21 bits	Output	Read address

Signal	Width	Direction	Description
ARLEN	4 bits	Output	Burst length
ARSIZE	3 bits	Output	Burst size
ARBURST	2 bits	Output	Burst type
ARLOCK	2 bits	Output	Lock type—Valid values are 00 (normal access) and 01 (exclusive access)
ARCACHE	4 bits	Output	Cache policy type
ARPROT	3 bits	Output	Protection type
ARVALID	1 bit	Output	Read address channel valid
ARREADY	1 bit	Input	Read address channel ready

Table 8-20: Lightweight HPS-to-FPGA Bridge Master Read Data Channel Signals

Signal	Width	Direction	Description
RID	12 bits	Input	Read ID
RDATA	32 bits	Input	Read data
RRESP	2 bits	Input	Read response
RLAST	1 bit	Input	Read last data identifier
RVALID	1 bit	Input	Read data channel valid
RREADY	1 bit	Output	Read data channel ready

Clocks and Resets

FPGA-to-HPS Bridge Clocks and Resets

The master interface of the bridge in the HPS logic operates in the `l3_main_clk` clock domain. The slave interface exposed to the FPGA fabric operates in the `f2h_axi_clk` clock domain provided by the user logic. The bridge provides clock crossing logic that allows the logic in the FPGA to operate in any clock domain, asynchronous from the HPS.

The FPGA-to-HPS bridge has one reset signal, `fpga2hps_bridge_rst_n`. The reset manager drives this signal to FPGA-to-HPS bridge on a cold or warm reset.

  Information about the f2h_axi_clk clock

GPV Clocks

The FPGA-to-HPS and HPS-to-FPGA bridges have GPV slave interfaces, mastered by the lightweight HPS-to-FPGA bridge. These interfaces operate in the `l4_mp_clk` clock domain. Even if you do not use the lightweight HPS-to-FPGA bridge in your FPGA design, you must ensure that a valid `l4_mp_clk` clock is being generated, so that the GPV registers in the HPS-to-FPGA and FPGA-to-HPS bridges can be programmed. The GPV logic in all three bridges is in the `l4_mp_clk` domain.

Related Information

The Global Programmers View on page 8-4

Data Width Sizing

The HPS-to-FPGA and FPGA-to-HPS bridges allow 32-, 64-, and 128-bit interfaces to be exposed to the FPGA fabric. For 32-bit and 128-bit interfaces, the bridge performs data width conversion to the fixed 64-bit interface within the HPS. This conversion is called *upsizing* in the case of data being converted from a 64-bit interface to a 128-bit interface. It is called *downsizing* in the case of data being converted from a

64-bit interface to a 32-bit interface. If an exclusive access is split into multiple transactions, the transactions lose their exclusive access information.

During the upsizing or downsizing process, transactions can also be resized using a data merging technique. For example, in the case of a 32-bit to 64-bit upsizing, if the size of each beat entering the bridge's 32-bit interface is only two bytes, the bridge can merge up to four beats to form a single 64-bit beat. Similarly, in the case of a 128-bit to 64-bit downsizing, if the size of each beat entering the bridge's 128-bit interface is only four bytes, the bridge can merge two beats to form a single 64-bit beat.

The bridges do not perform transaction merging for accesses marked as noncacheable.

Note: You can set the `bypass_merge` bit in the GPV to prevent the bridge from merging data and responses. If the bridge merges multiple responses into a single response, that response is the one with the highest priority. The response types have the following priorities:

1. DECERR
2. SLVERR
3. OKAY

HPS-FPGA Bridges Address Map and Register Definitions

The address map and register definitions for the HPS-FPGA bridges consist of the following regions:

Cortex-A9 Microprocessor Unit Subsystem 9

2014.06.30

cv_54006 Subscribe Send Feedback

The hard processor system (HPS) in the Altera SoC device includes a stand-alone, full-featured ARM Cortex-A9 MPCore™, single- or dual-core 32-bit application processor. The Cortex-A9 microprocessor unit (MPU) subsystem is composed of a Cortex-A9 MPCore, a level 2 (L2) cache, an Accelerator Coherency Port (ACP) ID mapper, and debugging modules.

Features of the Cortex-A9 MPU Subsystem

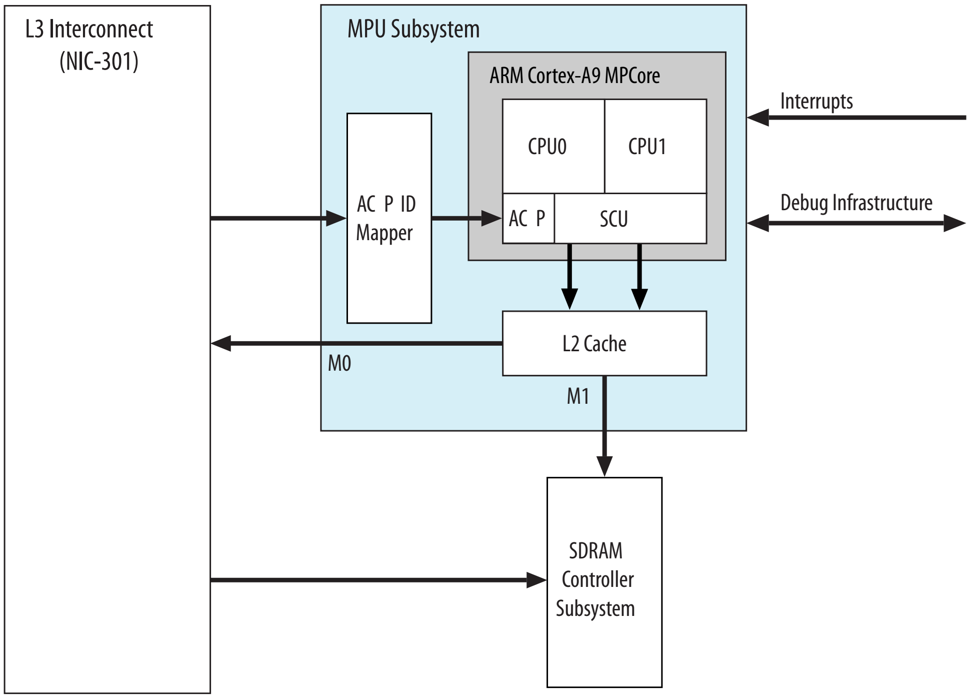
The Altera Cortex-A9 MPU subsystem provides the following features:

- One or two ARM Cortex-A9 processors each with the following support modules:
  - ARM NEON™ single instruction, multiple data (SIMD) coprocesoor
  - MMU
  - 32 KB instruction cache
  - 32 KB data cache
  - Private interval timer
  - Private watchdog timer
- Interrupt controller
- Global timer
- Snoop control unit (SCU)
- Accelerator Coherency Port (ACP)
- ARM L2 cache controller
- TrustZone® system security extensions
- Symmetric multiprocessing (SMP) and asymmetric multiprocessing (AMP) modes
- Debugging modules

Cortex-A9 MPU Subsystem Block Diagram and System Integration

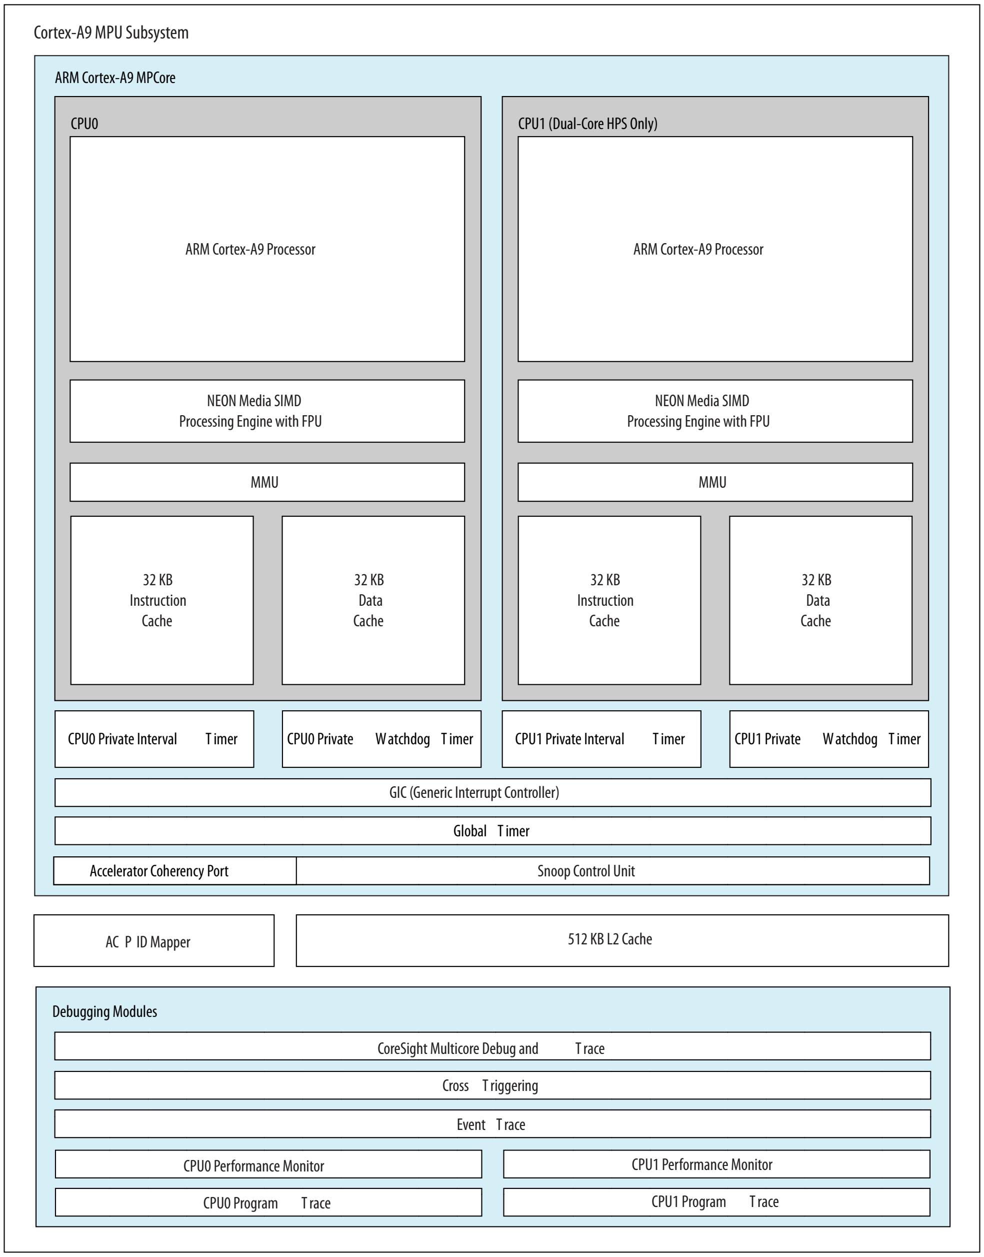
Cortex-A9 MPU Subsystem with L3 Interconnect

This block diagram shows a dual-core MPU subsystem in the context of the HPS, with the L2 cache. The L2 cache can access either the level 3 (L3) interconnect fabric or the SDRAM.



Cortex-A9 MPU Subsystem Internals

This figure shows a block diagram of the Altera Cortex-A9 MPU subsystem.



Cortex-A9 MPCore

The MPU subsystem includes a stand-alone, full-featured ARM Cortex-A9 MPCore single- or dual-core 32-bit application processor. The processor, like other HPS masters, can access IP in the FPGA fabric through the HPS-to-FPGA bridges.

Functional Description

The ARM Cortex-A9 MPCore contains the following blocks:

- One or two Cortex-A9 Revision r3p0 processors operating in SMP or AMP mode
- Snoop control unit (SCU)
- Private interval timer for each processor core
- Private watchdog timer for each processor core
- Global timer
- Interrupt controller

Each transaction originating from the Altera Cortex-A9 MPU subsystem can be flagged as secure or nonsecure.

Implementation Details

Table 9-1: Cortex-A9 MPCore Processor Configuration

This table shows the parameter settings for the Altera Cortex-A9 MPCore.

Feature	Options
Cortex-A9 processors	1 or 2
Instruction cache size per Cortex-A9 processor	32 KB
Data cache size per Cortex-A9 processor	32 KB
TLB size per Cortex-A9 processor	128 entries
Media Processing Engine with NEON™ technology per Cortex-A9 processor[13]	Included
Preload Engine per Cortex-A9 processor	Included
Number of entries in the Preload Engine FIFO per Cortex-A9 processor	16
Jazelle DBX extension per Cortex-A9 processor	Full
PTM interface per Cortex-A9 processor	Included
Support for parity error detection [14]	Included
Master ports	Two
Accelerator Coherency Port	Included

Related Information

http://infocenter.arm.com/

[13] Includes support for floating-point operations.

[14] For a description of the parity error scheme and parity error signals, refer to the Cortex-A9 Technical Reference Manual, available on the ARM website (infocenter.arm.com).

Cortex-A9 Processor

Each Cortex-A9 processor includes the following hardware blocks:

- ARM NEON™ single instruction, multiple data (SIMD) coprocessor with vector floating-point (VFP) v3 double-precision floating point unit for media and signal processing acceleration
  - Single- and double-precision IEEE-754 floating point math support
  - Integer and polynomial math support
- Level 1 (L1) cache with parity checking
  - 32 KB four-way set-associative instruction cache
  - 32 KB four-way set-associative data cache
- CoreSight™ Program Trace Macrocell (PTM) supporting instruction trace

Each Cortex-A9 processor supports the following features:

- Dual-issue superscalar pipeline with advanced branch prediction
- Out-of-order (OoO) dispatch and speculative instruction execution
- 2.5 million instructions per second (MIPS) per MHz, based on the Dhrystone 2.1 benchmark
- 128-entry translation lookaside buffer (TLB)
- TrustZone security extensions
- Configurable data endianness
- Jazelle® DBX Extensions for byte-code dynamic compiler support
- The Cortex-A9 processor architecture supports the following instruction sets:
  - The ARMv7-A performance-optimized instruction set
  - The memory-optimized Thumb®-2 mixed instruction set
    - Improves energy efficiency
    - 31% smaller memory footprint
    - 38% faster than the original Thumb instruction set
  - The Thumb instruction set—supported for legacy applications
- Each processor core in the Altera HPS includes a memory management unit (MMU) to support the memory management requirements of common modern operating systems.

The Cortex-A9 processors are designated CPU0 and CPU1.

Related Information

http://infocenter.arm.com/
Detailed documentation of ARM Cortex-A9 series processors is available on the ARM Infocenter website.

Reset

When a cold or warm reset is issued in the MPU, CPU0 is released from reset automatically, If CPU1 is present, then its reset signals are left asserted when a cold or warm reset is issued. After CPU0 comes out of reset, it can deassert CPU1's reset signals by clearing the `CPU1` bit in the MPU Module Reset (`mpumodrst`) register.

Related Information

Reset Manager on page 3-1

Interactive Debugging Features

Each Cortex-A9 processor has built-in debugging capabilities, including six hardware breakpoints (two with Context ID comparison capability) and four watchpoints. The interactive debugging features can be controlled by external JTAG tools or by processor-based monitor code.

Related Information

http://infocenter.arm.com/

For more information about the interactive debugging system, refer to the *Debug* chapter of the Cortex-A9 Technical Reference Manual, available on the ARM Infocenter website.

L1 Caches

Cache memory that is closely coupled with an associated processor is called level 1, or L1 cache. Each Cortex-A9 processor has two independent 32 KB L1 caches—one for instructions and one for data—allowing simultaneous instruction fetches and data access. Each L1 cache is four-way set associative, with 32 bytes per line, and supports parity checking.

Preload Engine

The preload engine (PLE) is a hardware block that enables the L2 cache to preload selected regions of memory.

The PLE signals the L2 cache when a cache line is needed in the L2 cache, by making the processor data master port start fetching the data. The processor data master does not complete the fetch or return the data to the processor. However, the L2 cache can then proceed to load the cache line. The data is only loaded to the L2 cache, not to the L1 cache or processor registers.

The preload functionality is under software control. The following PLE control parameters must be programmed:

- Programmed parameters, including the following:
  - Base address
  - Length of stride
  - Number of blocks
- A valid bit
- TrustZone memory protection for the cache memory, with an NS (non-secure) state bit
- A translation table base (TTB) address
- An Address Space Identifier (ASID) value

Related Information

http://infocenter.arm.com/

For more information about the PLE, refer to the *Preload Engine* chapter of the *Cortex-A9 Technical Reference Manual*, available on the ARM Infocenter website.

Floating Point Unit

Each ARM® Cortex-A9 processor includes full support for IEEE-754 floating point operations.

The floating-point unit (FPU) fully supports half-, single-, and double-precision variants of the following operations:

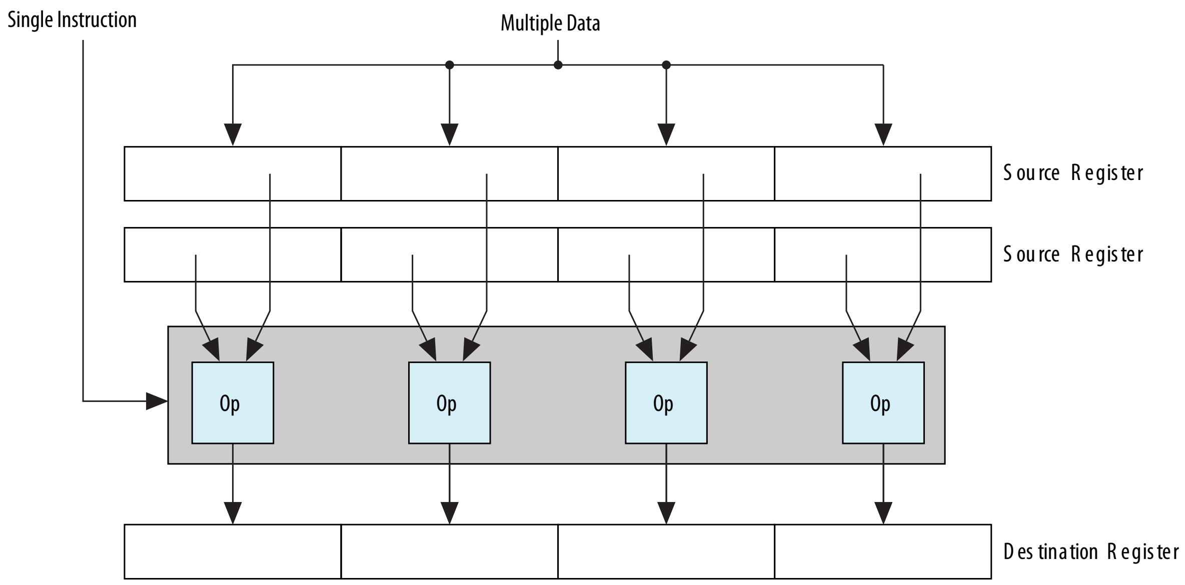
- Add
- Subtract
- Multiply
- Divide
- Multiply and accumulate (MAC)
- Square root

The FPU also converts between floating-point data formats and integers, including special operations to round towards zero required by high-level languages.

NEON Multimedia Processing Engine

The NEON™ multimedia processing engine (MPE) provides hardware acceleration for media and signal processing applications. Each ARM Cortex-A9 processor includes an ARM NEON MPE that supports SIMD processing.

Single Instruction, Multiple Data (SIMD) Processing



Features of the NEON MPE

The NEON™ processing engine accelerates multimedia and signal processing algorithms such as video encoding and decoding, 2-D and 3-D graphics, audio and speech processing, image processing, telephony, and sound synthesis.

The Cortex-A9 NEON MPE performs the following types of operations:

- SIMD and scalar single-precision floating-point computations
- Scalar double-precision floating-point computation
- SIMD and scalar half-precision floating-point conversion
- 8-bit, 16-bit, 32-bit, and 64-bit signed and unsigned integer SIMD computation
- 8-bit or 16-bit polynomial computation for single-bit coefficients

The following operations are available:

- Addition and subtraction
- Multiplication with optional accumulation (MAC)
- Maximum or minimum value driven lane selection operations
- Inverse square root approximation
- Comprehensive data-structure load instructions, including register-bank-resident table lookup

Related Information

http://infocenter.arm.com/
For more information about the Cortex-A9 NEON MPE, refer to the Cortex-A9 NEON™ Media Processing Engine Technical Reference Manual, which you can download from the ARM Infocenter website.

Memory Management Unit

The MMU is used in conjunction with the L1 and L2 caches to translate virtual addresses used by software to physical addresses used by hardware. Each processor has a private MMU.

TLBs Supported By the MMU

TLB Type	Memory Type	Number of Entries	Associativity
Micro TLB	Instruction	32	Fully associative
Micro TLB	Data	32	Fully associative
Main TLB	Instruction and Data	128	Two-way associative

TLB Features

The main TLB has the following features:

- Lockable entries using the lock-by-entry model
- Supports hardware page table walks to perform look-ups in the L1 data cache

The MPU address map is divided into the following regions:

- The boot region
- The SDRAM region
- The FPGA slaves region
- The HPS peripherals region

Related Information

http://infocenter.arm.com/
For more information about the MMU, refer to the *Memory Management Unit* chapter of the *Cortex-A9 Technical Reference Manual*, available on the ARM Infocenter website.

The Boot Region

The boot region is 1 MB in size, based at address 0. After power-on, or after reset of the L3 interconnect, the boot region is occupied by the boot ROM, allowing the Cortex-A9 MPCore to boot. Although the boot region size is 1 MB, accesses beyond 64 KB are illegal because the boot ROM is only 64 KB.

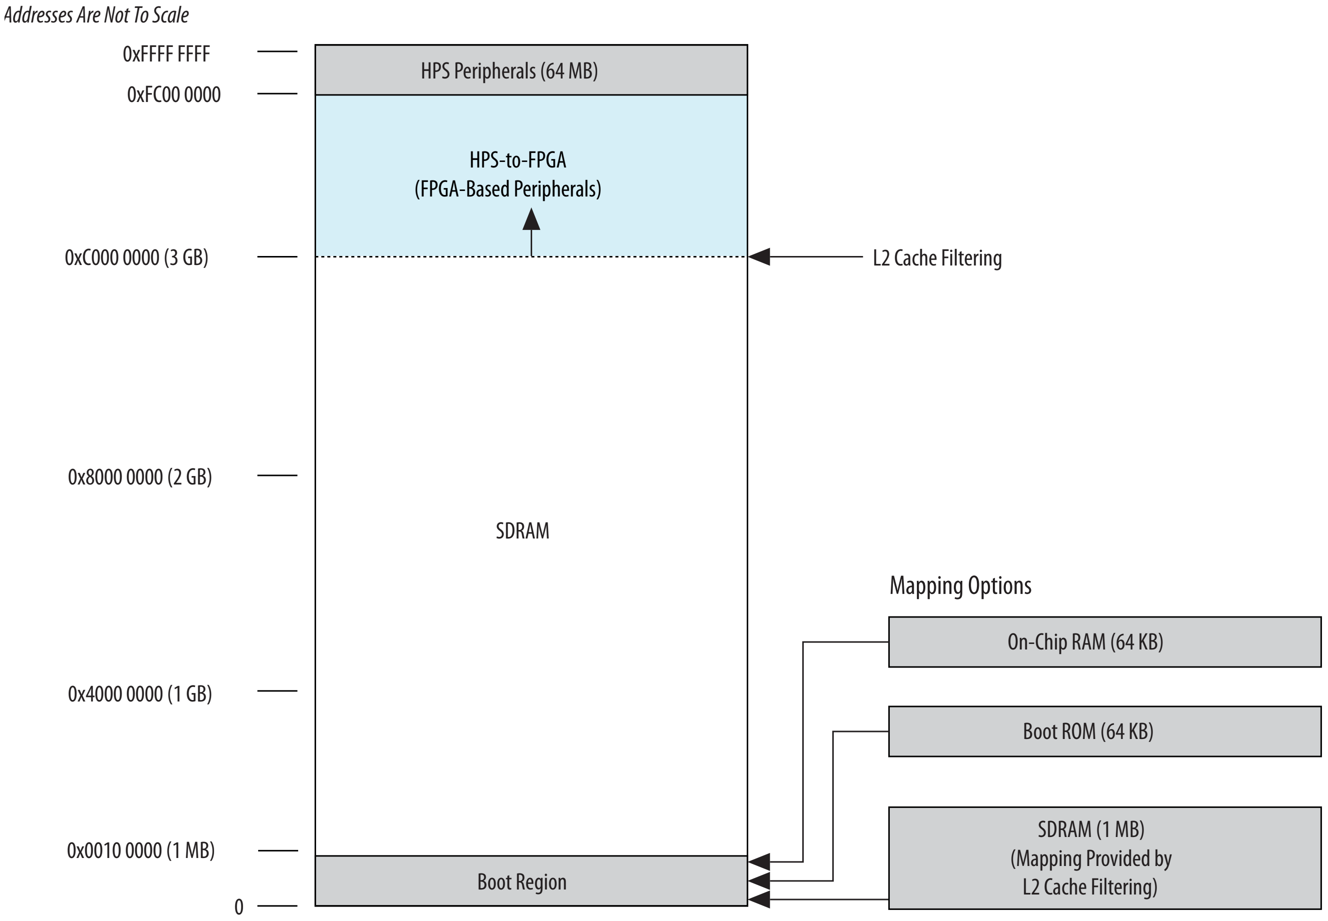
The 1 MB boot region can be subsequently remapped to the bottom 1 MB of SDRAM region.

Note: Alternatively, the boot region can be mapped to the 64 KB on-chip RAM.

Related Information

- **The SDRAM Region** on page 9-11
- **System Interconnect** on page 7-1

The MPCore Address Map



The SDRAM Region

The SDRAM region starts at address `0x100000` (1 MB). The top of the region is determined by the L2 cache filter.

The L2 cache contains a filtering mechanism that routes accesses to the SDRAM and L3 interconnect. The filter defines a filter range with start and end addresses. Any access within this filter range is routed to the SDRAM subsystem. Accesses outside of this filter range are routed to the L3 interconnect.

The start and end addresses are specified in the following register fields:

- `reg12_addr_filtering_start.address_filtering_start`
- `reg12_address_filtering_end.address_filtering_end`

To remap the lower 1MB of SDRAM into the boot region, set the filter start address to `0x0` to ensure accesses between `0x0` and `0xFFFFF` are routed to the SDRAM. Independently, you can set the filter end address in 1 MB increments above `0xC0000000` to extend the upper bounds of the SDRAM region. However, you achieve this extended range at the expense of the FPGA peripheral address span. Depending on the address filter settings in the L2 cache, the top of the SDRAM region can range from `0xBFFFFFFF` to `0xFBFFFFFF`.

Related Information

L2 Cache on page 9-50

The FPGA Slaves Region

The Cortex-A9 MPU subsystem supports the variable-sized FPGA slaves region to communicate with FPGA-based peripherals. This region can start as low as `0xC0000000`, depending on the L2 cache filter settings. The top of the FPGA slaves region is located at `0xFBFFFFFF`. As a result, the size of the FPGA slaves region can range from 0 to `0x3F000000` bytes.

The HPS Peripherals Region

The HPS peripherals region is the top 64 MB in the address space, starting at `0xFC000000` and extending to `0xFFFFFFFF`. The HPS peripherals region is always allocated to the HPS dedicated peripherals for the Altera Cortex-A9 MPU subsystem.

Performance Monitoring Unit

Each Cortex-A9 processor has a Performance Monitoring Unit (PMU). The PMU supports 58 events to gather statistics on the operation of the processor and memory system. Six counters in the PMU accumulate the events in real time. The PMU counters are accessible either from the processor itself, using the Coprocessor 14 (CP14) interface, or from an external debugger. The events are also supplied to the PTM and can be used for trigger or trace.

Related Information

http://infocenter.arm.com/
For more information about the PMU, refer to the *Performance Monitoring Unit* chapter of the *Cortex-A9 Technical Reference Manual*, available on the ARM Infocenter website.

MPCore Timers

There is one interval timer and one watchdog timer for each processor.

Functional Description

Each timer is private, meaning that only its associated processor can access it. If the watchdog timer is not needed, it can be configured as a second interval timer.

Each private interval and watchdog timer has the following features:

- A 32-bit counter that optionally generates an interrupt when it reaches zero
- Configurable starting values for the counter
- An eight-bit prescaler value to qualify the clock period

Implementation Details

The timers are configurable to either single-shot or auto-reload mode. The timer blocks are clocked by `mpu_periph_clk`, running at ¼ the rate of `mpu_clk`.

Related Information

http://infocenter.arm.com/
For more information about private timers, refer to “About the private timer and watchdog blocks” in the *Global timer, Private timers, and Watchdog registers* chapter of the *Cortex-A9 MPCore Technical Reference Manual*, available on the ARM Infocenter website.

Generic Interrupt Controller

Functional Description

The Generic Interrupt Controller (GIC) supports up to 180 interrupt sources, including dedicated peripherals and IP implemented in the FPGA fabric. In a dual-core system, the GIC is shared by both Cortex-A9 processors. Each processor also has 16 banked software-generated interrupts and 16 banked private peripheral interrupts, which occupy interrupt numbers 0 to 31.

Implementation Details

The configuration and control for the GIC is memory-mapped and accessed through the SCU. The GIC are clocked by `mpu_periph_clk`, running at ¼ the rate of `mpu_clk`.

Global Timer

The MPU features a global 64-bit, auto-incrementing timer, which is primarily used by the operating system.

Functional Description

The global timer is accessible by the processors using memory-mapped access through the SCU. The global timer has the following features:

- 64-bit incrementing counter with an auto-incrementing feature. It continues incrementing after sending interrupts.
- Memory-mapped in the private memory region.
- Accessed at reset in Secure State only. It can only be set once, but secure code can read it at any time.
- Accessible to both Cortex-A9 processors in the MPCore.

Implementation Details

Each Cortex-A9 processor has a private 64-bit comparator that generates a private interrupt when the counter reaches the specified value. Each Cortex-A9 processor uses the banked ID, ID27, for this interrupt. ID27 is sent to the GIC as a Private Peripheral Interrupt (PPI).

The global timer are clocked by mpu_periph_clk, running at ¼ the rate of mpu_clk.

Related Information

For more information about the global timer, refer to "About the Global Timer" in the *Global timer, Private timers, and Watchdog registers* chapter of the Cortex-A9 MPCore Technical Reference Manual, available on the ARM Infocenter website.

Snoop Control Unit

The SCU manages data traffic for the Cortex-A9 processors and the memory system, including the L2 cache. In a multi-master system, the processors and other masters can operate on shared data. The SCU ensures that each processor operates on the most up-to-date copy of data, maintaining cache coherency.

Functional Description

The SCU is used to connect the Cortex-A9 processors and the ACP to the L2 cache controller. The SCU performs the following functions:

- When the processors are set to SMP mode, the SCU maintains data cache coherency between the processors.

  Note: The SCU does not maintain coherency of the instruction caches.
- Initiates L2 cache memory accesses
- Arbitrates between processors requesting L2 access
- Manages ACP access with cache coherency capabilities.

Accelerator Coherency Port on page 9-25

Implementation Details

When the processor writes to any coherent memory location, the SCU ensures that the relevant data is coherent (updated, tagged, or invalidated). Similarly, the SCU monitors read operations from a coherent memory location. If the required data is already stored within the other processor's L1 cache, the data is returned directly to the requesting processor. If the data is not in L1 cache, the SCU issues a read to the L2 cache. If the data is not in the L2 cache memory, the read is finally forwarded to main memory. The primary goal is to minimize power consumption and maximize overall memory performance.

The SCU maintains bidirectional coherency between the L1 data caches belonging to the processors. When one processor writes to a location in its L1 cache, if the same location is cached in the other L1 cache, the SCU updates it.

Non-coherent data passes through as a standard read or write operation.

The SCU also arbitrates between the Cortex-A9 processors if both attempt simultaneous access to the L2 cache, and manages accesses from the ACP.

Accelerator Coherency Port

The ACP allows peripherals—including FPGA-based peripherals—to maintain data coherency with the Cortex-A9 MPCore processors and the SCU. Dedicated peripherals in the HPS, and those built in FPGA logic, access the coherent memory through the ACP ID mapper and the ACP.

Note: The entire 4 GB address space can be accessed coherently through the ACP.

The high-bandwidth peripherals, including the FPGA data ports, connect to the L3 interconnect.

Burst Sizes and Byte Strobes

The ACP improves system performance for hardware accelerators in the FPGA fabric. However, in order to achieve high levels of performance, you must use the one of the recommended burst types. The other burst types have significantly lower performance.

Related Information

Recommended Burst Types on page 9-25

Recommended Burst Types

Table 9-3: Recommended Burst Types

Burst Type	Beats	Width (Bits)	Address Type	Byte Strobes
Wrapping	4	64	64-bit aligned	Asserted
Incrementing	4	64	32-bit aligned	Asserted

Related Information

Burst Sizes and Byte Strobes on page 9-25

Burst Guidelines

Note: If the slave port of the FPGA-to-HPS bridge is not 64 bits wide, you must supply bursts to the FPGA-to-HPS bridge that are upsized or downsized to the burst types above. For example, if the slave data width of the FPGA-to-HPS bridge is 32 bits, then bursts of eight beats by 32 bits are required to access the ACP efficiently.

Note: If the address and burst size of the transaction to the ACP matches either of the conditions above, the logic in the MPU assumes the transaction has all its byte strobes set. If the byte strobes are not all set, then the write does not actually overwrite all the bytes in the word. Instead, the cache assumes the whole cache line is valid. If this line is dirty (and therefore gets written out to SDRAM), data corruption might occur.

Exclusive and Locked Accesses

The ACP does not support exclusive accesses to coherent memory. The ACP supports exclusive accesses to non-coherent memory; however, it is important that the exclusive access transaction is not affected by the upsizing and downsizing logic of the FPGA-to-HPS bridge or the L3 interconnect. If the exclusive access is broken into multiple transactions due to the sizing logic, the exclusive access bit is cleared by the bridge or interconnect and the exclusive access fails.

Note: Altera recommends that exclusive accesses bypass the ACP altogether, either through the 32-bit slave port of the SDRAM controller connected directly to the L3 interconnect or through the FPGA-to-SDRAM interface.

The ACP ID mapper does not support locked accesses. To ensure mutually exclusive access to shared data, use the exclusive access support built into the SDRAM controller.

Related Information

  For more information about the exclusive access support of the SDRAM controller subsystem, refer to the *SDRAM Controller Subsystem* chapter.
- **Functional Description—HPS Memory Controller** on page 11-1

ACP ID Mapper

The ACP ID mapper is situated between the level 3 (L3) interconnect and the MPU subsystem ACP slave. It is responsible for mapping 12-bit Advanced Microcontroller Bus Architecture (AMBA®) Advanced eXtensible Interface (AXI™) IDs (input IDs) from the L3 interconnect to 3-bit AXI IDs (output IDs) supported by the ACP slave port.

The ACP ID mapper also implements a 1 GB coherent window into 4 GB MPCore.

Functional Description

The ACP slave supports up to six masters. However, custom peripherals implemented in the FPGA fabric can have a larger number of masters that need to access the ACP slave. The ACP ID mapper allows these masters to access the ACP.

The ACP ID mapper resides between the interconnect and the ACP slave of the MPU subsystem. It has the following characteristics:

- Support for up to six concurrent ID mappings
- 1 GB coherent window into 4 GB MPCore address space
- Remaps the 5-bit user sideband signals used by the Snoop Control Unit (SCU) and L2 cache.

Related Information

http://infocenter.arm.com/
For more information about AXI user sideband signals, refer to the CoreLink Level 2 Cache Controller L2C-310 Technical Reference Manual, which you can download from the ARM Infocenter website.

Implementation Details

The ACP is accessed by masters that require access to coherent memory. The ACP slave port can be accessed by the master peripherals of the L3 interconnect, as well as by masters implemented in the FPGA fabric (via the FPGA-to-HPS bridge).

The ACP ID mapper supports the following ID mapping modes:

- Dynamic mapping
- Fixed mapping

Software can select the ID mapping on a per-ID basis. For input IDs that are configured for fixed mapping, there is a one-to-one mapping from input IDs to output IDs. When an input ID is configured for dynamic mapping, it is automatically mapped to an available output ID. The dynamic mode is more flexible because the hardware handles the mapping. The hardware mapping allows you to use one output ID for more than one input ID. Output IDs are assigned to input IDs on a first-come, first-served basis.

Out of the total of eight output IDs, only six are available to masters of the L3 interconnect. The first two output IDs (0 and 1) are dedicated to the Cortex-A9 processor cores in the MPU subsystem, leaving the last six output IDs (2-7) available to the ACP ID mapper. Output IDs 2-6 support fixed and dynamic modes of operation while output ID 7 supports dynamic only.

The operating modes are programmable through accesses to the control and status registers in the ACP ID mapper. At reset time, the ACP ID mapper defaults to dynamic ID mapping for all output IDs except ID 2, which resets to a fixed mapping for the Debug Access Port (DAP) input ID.

Related Information

Cortex-A9 MPU Subsystem with L3 Interconnect on page 9-2
This block diagram shows a dual-core MPU subsystem in the context of the HPS, with the L2 cache. The L2 cache can access either the level 3 (L3) interconnect fabric or the SDRAM.

ID Intended Usage

Table 9-4 summarizes the expected usage of the 3-bit output IDs, and their settings at reset.

Table 9-4: ID Intended Usage

Output ID	Reset State	Intended Use
7	Dynamic	Dynamic mapping only

Output ID	Reset State	Intended Use
6	Dynamic	Fixed or dynamic, programmed by software.
5		
4		
3		
2	Statistically assigned to DAP (ID 0x005)	Assigned to the input ID of the DAP at reset. After reset, can be either fixed or dynamic, programmed by software.
1	—	Not used by the ACP ID Mapper
0		

AXI User Sideband Override

For masters that cannot drive the AXI user sideband signal of incoming transactions, the ACP ID mapper can control overriding this signal. The ACP ID mapper can also control which 1 GB coherent window into memory is accessed by masters of the L3 interconnect. Each fixed mapping can be assigned a different user sideband signal and memory window to allow specific settings for different masters. All dynamic mappings share a common user sideband signal and memory window setting.

Transaction Capabilities

At any one time, the ACP ID mapper can accept and issue up to 15 transactions per ID mapping. Read and write ID mappings are managed in separate lists, allowing more unique input IDs to be remapped at any given time. If a master issues a series of reads and writes with the same input ID, there are no ordering restrictions.

Because there are only six output IDs available, there can be no more than six read and six write transactions with unique IDs in progress at any one time. The write acceptance of the ACP slave is five transactions, and the read acceptance is 13 transactions. Only four coherent read transactions per ID mapping can be outstanding at one time.

Dynamic Mapping Mode

In dynamic mode, every unique input ID that is received from the L3 master port is assigned to an unused output ID. The new output ID is applied to the transaction as it is issued to the ACP slave of the SCU. Any transaction that arrives to the ACP ID mapper with an input ID that matches an already-in-progress transaction is mapped to the same output ID. Once all transactions on an ID mapping have completed, that output ID is released and can be used again for other input IDs.

Fixed Mapping Mode

In fixed mode, output IDs 2 through 6 can be assigned by software to a specific 12-bit input ID. This ability makes it possible to use the lock-by-master feature of the L2 cache controller, because the input transaction ID from the master is always assigned to a specific output ID. Unlike dynamic mode, ID 7 is not available for fixed mapping because it is reserved for dynamic mode only to avoid system deadlocks.

The ACP ID mapper has two banks of registers to control the behavior of the mappings, namely, a request bank and a read-only status bank. Both banks contain the same number of registers. To change the settings for a particular mapping (either a specific fixed ID, or all dynamic mappings), software should write to the appropriate register in the request bank. The hardware examines the request, and only applies the change when safe to do so, which is when there are no outstanding transactions with the output ID. When the change is applied, the status register is updated. Software should check that the change has actually taken place by polling the corresponding status register.

HPS Peripheral Master Input IDs

Table 9-5: HPS Peripheral Master Input IDs

The input IDs issued from the interconnect for each HPS peripheral master that can access the ACP ID mapper

Interconnect Master	ID [15]
L2M0	`0xxx xxxx x010`
DMA	`0000 0xxx x001`
EMAC0	`1000 0xxx x001`
EMAC1	`1000 0xxx x010`
USB0	`1000 0000 0011`
USB1	`1000 0000 0110`
NAND	`1xxx xxxx x100`
ETR	`1000 0000 0000`
DAP	`0000 0000 0100`
SD/MMC	`1000 0000 0101`
FPGA-to-HPS bridge	`0xxx xxxx x000`

Control of the AXI User Sideband Signals

The ACP ID mapper module allows control of the AXI user sideband signal values. Not all masters drive these signals, so the ACP ID mapper makes it possible to drive the 5-bit user sideband signal with either a default value (in dynamic mode) or specific values (in fixed mode). The sideband signals are controlled

[15] Values are in binary. The letter *x* denotes variable ID bits each master passes with each transaction.

through the ACP port. Sideband signals `AWUSER[4:1]` convey the inner cache attributes and `AWUSER[0]` determines whether the transaction is a shared cache access.

There are registers available to configure the default values of the user sideband signals for all transactions, and fixed values of these signals for particular transactions in fixed mapping mode. In dynamic mode, the user sideband signals of incoming transactions are mapped with the default values stored in the register. In fixed mapping mode, the input ID of the transaction is mapped to the 3-bit output ID and the user sideband signals of the transaction are mapped with the values stored in the register that corresponds to the output ID. One important exception, however, is that the ACP ID mapper always allows user sideband signals from the FPGA-to-HPS bridge to pass through to the ACP regardless of the user sideband value associated with the ID.

Memory Region Remap

The ACP ID mapper has 1 GB of address space, which is by default a view into the bottom 1 GB of SDRAM. The mapper also allows transactions to be routed to different 1 GB-sized memory regions, called pages, in both dynamic and fixed modes. The two most significant bits of incoming 32-bit AXI address signals are replaced with the 2-bit user-configured address page decode information. The page decoder uses the values shown in **Table 9-6**.

Table 9-6: Page Decoder Values

Page	Address Range
0	`0x00000000–0x3FFFFFFF`
1	`0x40000000–0x7FFFFFFF`
2	`0x80000000–0xBFFFFFFF`
3	`0xC0000000–0xFFFFFFFF`

With this page decode information, a master can read or write to any 1 GB region of the 4 GB memory space while maintaining cache coherency with the MPU subsystem.

Using this feature, a debugger can have a coherent view into main memory, without having to stop the processor. For example, at reset the DAP input ID (0x001) is mapped to output ID 2, so the debugger can vary the 1 GB window that the DAP accesses without affecting any other traffic flow to the ACP.

ACP ID Mapper Address Map and Register Definitions

This section lists the ACP ID Mapper register address map and describes the registers.

L2 Cache

The MPU subsystem includes a secondary 512 KB L2 shared, unified cache memory.

Functional Description

The L2 cache is much larger than the L1 cache. The L2 cache has significantly lower latency than external memory. The L2 cache is up to eight-way associative, configurable down to one-way (direct mapped). Like the L1 cache, the L2 cache can be locked by cache line, locked by way, or locked by bus master.

The L2 cache implements error correction codes (ECCs) and ECC error reporting. The cache can report a number of events to the processor and operating system.

Cache Controller Configuration

The L2 cache consists of the ARM L2C-310 L2 cache controller configured as follows:

- 512 KB total memory
- Eight-way associativity
- Physically addressed, physically tagged
- Line length of 32 bytes
- Critical first word linefills
- Support for all AXI cache modes
    - Write-through
    - Write-back
    - Read allocate
    - Write allocate
    - Read and write allocate

- Single event upset (SEU) protection
  - Parity on Tag RAM
  - ECC on L2 Data RAM
- Two slave ports mastered by the SCU
- Two master ports connected to the following slave ports:
  - SDRAM controller, 64-bit slave port width
  - L3 interconnect, 64-bit slave port width
- Cache lockdown capabilities as follows:
  - Line lockdown
  - Lockdown by way
  - Lockdown by master (both processors and ACP masters)
- TrustZone support
- Cache event monitoring

Related Information

  For more information about AXI user sideband signals, refer to the CoreLink Level 2 Cache Controller L2C-310 Technical Reference Manual, which you can download from the ARM Infocenter website.

L2 Cache Address Filtering

The L2 cache can access either the L3 interconnect fabric or the SDRAM. The L2 cache address filtering determines how much address space is allocated to the HPS-to-FPGA bridge and how much is allocated to SDRAM, depending on the configuration of the memory management unit.

Related Information

- **Cortex-A9 MPU Subsystem with L3 Interconnect** on page 9-2
This block diagram shows a dual-core MPU subsystem in the context of the HPS, with the L2 cache. The L2 cache can access either the level 3 (L3) interconnect fabric or the SDRAM.
- **Memory Management Unit** on page 9-9
  Information about how the address space is set based on L2 cache address filtering.

ECC Support

The L2 cache has the option of using ECCs to protect against SEU errors in the cache RAM.

Enabling ECCs does not affect the performance of the L2 cache. The ECC bits are calculated only for writes to the data RAM that are 64 bits wide (8 bytes, or one-quarter of the cache line length). The ECC logic does not perform a read-modify-write when calculating the ECC bits.

The ECC protection bits are not valid in the following cases:

- Data is written that is not 64-bit aligned in memory
- Data is written that is less than 64 bits in width

In these cases the Byte Write Error interrupt is asserted. Cache data is still written when such an error occurs. However, the ECC error detection and correction continues to function. Therefore, the cache data is likely to be incorrect on subsequent reads.

To use ECCs, the software and system must meet the following requirements:

- L1 and L2 cache must be configured as write-back and write-allocate for any cacheable memory region
- Level 3 interconnect masters using the ACP must only perform the following types of data writes:
  - 64-bit aligned in memory
  - 64-bit wide accesses

  Note that L3 interconnect masters can include masters in the FPGA accessing the FPGA-to-HPS bridge.

If a correctable ECC error occurs, the ECC corrects the read data in parallel to asserting a correctable error signal on the AXI bus. If an uncorrectable error occurs in the L2 cache, the uncorrected data remains in the L2 cache and an AXI slave error (SLVERR) is sent to the L1 memory system. In addition, interrupts can be enabled for correctable and uncorrectable ECC errors through the GIC.

Related Information

System Manager on page 5-1
For more information about SEU errors, refer to the *System Manager* chapter.

Implementation Details

The following table shows the parameter settings for the cache controller.

Table 9-7: Cache Controller Configuration

Feature	Meaning
Cache way size	64 KB
Number of cache ways	8 ways
Tag RAM write latency	1
Tag RAM read latency	1
Tag RAM setup latency	1
Data RAM write latency	1
Data RAM read latency	2
Data RAM setup latency	1
Parity logic	Parity logic enabled
Lockdown by master	Lockdown by master enabled

Feature	Meaning
Lockdown by line	Lockdown by line enabled
AXI ID width on slave ports	6 AXI ID bits on slave ports
Address filtering	Address filtering logic enabled
Speculative read	Logic for supporting speculative read enabled
Presence of ARUSERMx and AWUSERMx sideband signals	Sideband signals enabled

Related Information

http://infocenter.arm.com/

For further information about cache controller configurable options, refer to the CoreLink Level 2 Cache Controller L2C-310 Technical Reference Manual, available on the ARM Infocenter website.

L2 Cache Lockdown Capabilities

The L2 cache has three methods to lock data in the cache RAMs:

- Lockdown by line—Used to lock lines in the cache. This is commonly used for loading critical sections of software into the cache temporarily.
- Lockdown by way—Allows any or all of the eight cache ways to be locked. This is commonly used for loading critical data or code into the cache.
- Lockdown by master—Allows cache ways to be dedicated to a single master port. This allows a large cache to look like smaller caches to multiple master ports. The L2 cache can be mastered by CPU0, CPU1, or the six ACP masters, for a total of eight possible master ports.

Related Information

http://infocenter.arm.com/

For more information about L2 cache lockdown capabilities, refer to “Cache operation” in the *Functional Overview* chapter of the *CoreLink Level 2 Cache Controller L2C-310 Technical Reference Manual*, available on the ARM Infocenter website.

L2 Cache Event Monitoring

The L2 cache supports the built-in cache event monitoring signals shown in the table below. The L2 cache can count two of the events at any one time.

Table 9-8: L2 Cache Events

Event	Description
`CO`	Eviction (cast out) of a line from the L2 cache.
`DRHIT`	Data read hit in the L2 cache.

Event	Description
DRREQ	Data read lookup to the L2 cache. Subsequently results in a hit or miss.
DWHIT	Data write hit in the L2 cache.
DWREQ	Data write lookup to the L2 cache. Subsequently results in a hit or miss.
DWTREQ	Data write lookup to the L2 cache with write-through attribute. Subsequently results in a hit or miss.
EPFALLOC	Prefetch hint allocated into the L2 cache.
EPFHIT	Prefetch hint hits in the L2 cache.
EPFRCVDS0	Prefetch hint received by slave port S0.
EPFRCVDS1	Prefetch hint received by slave port S1.
IPFALLOC	Allocation of a prefetch generated by L2 cache controller into the L2 cache.
IRHIT	Instruction read hit in the L2 cache.
IRREQ	Instruction read lookup to the L2 cache. Subsequently results in a hit or miss.
SPNIDEN	Secure privileged non-invasive debug enable.
SRCONFS0	Speculative read confirmed in slave port S0.
SRCONFS1	Speculative read confirmed in slave port S1.
SRRCVDS0	Speculative read received by slave port S0.
SRRCVDS1	Speculative read received by slave port S1.
WA	Allocation into the L2 cache caused by a write (with write-allocate attribute) miss.

In addition, the L2 cache events can be captured and timestamped using dedicated debugging circuitry.

Related Information

http://infocenter.arm.com/
For more information about L2 event capture, refer to the *Debug* chapter of the Cortex-A9 MPCore Technical Reference Manual, available on the ARM Infocenter website.

Debugging Modules

The MPU subsystem includes debugging resources through ARM CoreSight on-chip debugging and trace. The following functionality is included:

- Individual program trace for each processor
- Event trace for the Cortex-A9 MPCore
- Cross triggering between processors and other HPS debugging features

Program Trace

Each processor has an independent PTM that provides real-time instruction flow trace. The PTM is compatible with a number of third-party debugging tools.

The PTM provides trace data in a highly compressed format. The trace data includes tags for specific points in the program execution flow, called waypoints. Waypoints are specific events or changes in the program flow.

The PTM recognizes and tags the waypoints listed in **Table 9-9**.

Table 9-9: Waypoints Supported by the PTM

Type	Additional Waypoint Information
Indirect branches	Target address and condition code
Direct branches	Condition code
Instruction barrier instructions	—
Exceptions	Location where the exception occurred
Changes in processor instruction set state	—
Changes in processor security state	—
Context ID changes	—
Entry to and return from debug state when Halting debug mode is enabled	—

The PTM optionally provides additional information for waypoints, including the following.

- Processor cycle count between waypoints
- Global timestamp values
- Target addresses for direct branches

Related Information

- **CoreSight Debug and Trace** on page 10-1

- **http://infocenter.arm.com/**
  For more information about the PTM, refer to the CoreSight PTM-A9 Technical Reference Manual, available on the ARM Infocenter website.

Event Trace

Events from each processor can be used as inputs to the PTM. The PTM can use these events as trace and trigger conditions.

Related Information

- **Performance Monitoring Unit** on page 9-12
- **http://infocenter.arm.com/**
  For more information about the trigger and trace capabilities, refer to the CoreSight PTM-A9 Technical Reference Manual, Revision r1p0, available on the ARM Infocenter website.

Cross-Triggering

The PTM can export trigger events and perform actions on trigger inputs. The cross-trigger signals interface with other HPS debugging components including the FPGA fabric. Also, a breakpoint in one processor can trigger a break in the other.

Related Information

CoreSight Debug and Trace on page 10-1
For detailed information about cross-triggering and about debugging hardware in the MPU, refer to the *CoreSight Debug and Trace* chapter.

Clocks

Four synchronous clocks and two debug clocks are provided to the MPU subsystem.

Table 9-10: MPU Subsystem Clocks

System Clock Name	Use
`mpu_clk`	Main clock for the MPU subsystem
`mpu_periph_clk`	Clock for peripherals inside the MPU subsystem
`mpu_l2_ram_clk`	Clock for the L2 cache and Accelerator Coherency Port (ACP) ID mapper
`l4_mp_clk`	Clock for the ACP ID mapper control slave
`dbg_at_clk`	Trace bus clock
`dbg_clk`	Debug clock

Cortex-A9 MPU Subsystem Register Implementation

The following configurations are available through registers in the Cortex-A9 subsystem:

- All processor-related controls, including the MMU and L1 caches, are controlled using the Coprocessor 15 (CP15) registers of each individual processor.
- All SCU registers, including control for the timers and GIC, are memory mapped.
- All L2 cache registers are memory-mapped.

Document Revision History

Date	Version	Changes
June 2014	2014.06.30	• Added Reset Section to Cortex-A9 Processor • Updated HPS Peripheral Master Input IDs table • Added ACP ID Mapper Address Map and Register Definitions • Added information in ECC Support section regarding ECC errors • Minor clarifications regarding MPU description and module revision numbers
February 2014	2014.02.28	Maintenance release
December 2013	2013.12.30	Correct SDRAM region address in MPCore Address Map
November 2012	1.2	Minor updates.
May 2012	1.1	• Add description of the ACP ID mapper • Consolidate redundant information

Date	Version	Changes
January 2012	1.0	Initial release.

CoreSight Debug and Trace 10

2014.07.31

cv_54007 Subscribe Send Feedback

The hard processor system (HPS) debug infrastructure provides visibility and control of the HPS modules, the ARM® Cortex®-A9 microprocessor unit (MPU) subsystem, and user logic implemented in the FPGA fabric. The debug system design incorporates ARM® CoreSight™ components.

Details of the ARM CoreSight debug components can be viewed by clicking on the related information links below.

Features of CoreSight Debug and Trace

The CoreSight debug and trace system offers the following features:

- Real-time program flow instruction trace through a separate PTM for each processor
- Host debugger JTAG interface
- Connections for cross-trigger and STM-to-FPGA interfaces, which enable soft IP generation of triggers and system trace messages
- Instruction trace interface through TPIU for trace analysis tools
- Custom message injection through STM into trace stream for delivery to host debugger

- STM and PTM trace sources multiplexed into a single stream through the Trace Funnel
- Capability to route trace data to any slave accessible to the ETR AXI master connected to the level 3 (L3) interconnect
- Capability for the following SoC modules to trigger each other through the embedded cross-trigger system:
  - FPGA fabric
  - A9-0 processor
  - A9-1 processor
  - PTM-0
  - PTM-1
  - STM
  - ETF
  - ETR
  - TPIU
  - csCTI
  - CTI-0
  - CTI-1
  - FPGA-CTI
  - csCTM
  - CTM

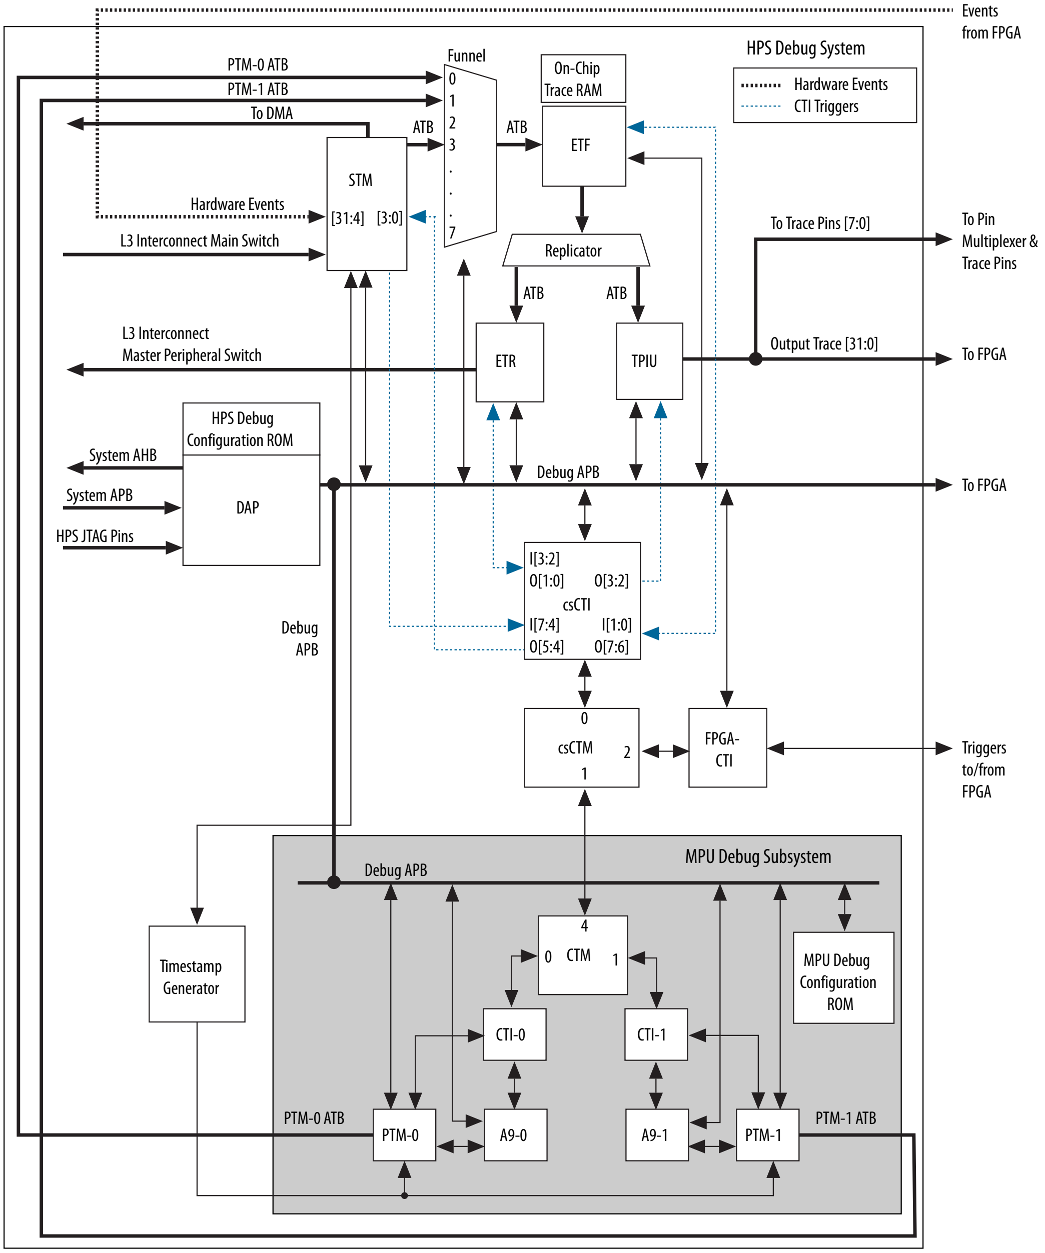
CoreSight Debug and Trace Block Diagram and System Integration

Figure 10-1: HPS CoreSight Debug and Trace System Block Diagram



Functional Description of CoreSight Debug and Trace

CoreSight systems provide all the infrastructure you require to debug, monitor, and optimize the performance of a complete HPS design. CoreSight technology addresses the requirement for a multicore debug and trace solution with high bandwidth for whole systems beyond the processor core.

CoreSight technology provides the following features:

- Cross-trigger support between SoC subsystems
- High data compression
- Multisource trace in a single stream
- Standard programming models for standard tool support

Related Information

http://infocenter.arm.com/
You can download the documents from the ARM info center website.

Debug Access Port (DAP)

The DAP provides the necessary ports for a host debugger to connect to and communicate with the HPS through a JTAG interface connected to dedicated HPS pins that is independent of the JTAG for the FPGA. The JTAG interface provided with the DAP allows a host debugger to access various modules inside the HPS. Additionally, a debug monitor executing on either processor can access different HPS components by interfacing with the system Advanced Microcontroller Bus Architecture (AMBA®) Advanced Peripheral Bus (APB™) slave port of the DAP. The system APB slave port occupies 2 MB of address space in the HPS. Both the JTAG port and system APB port have access to the debug APB master port of the DAP. As shown in **Figure 10-1**, all CoreSight components are connected to the debug APB.

A host debugger can access any HPS memory-mapped resource in the system via the DAP system master port. Requests made over the DAP system master port are impacted by reads and writes to peripheral registers.

Note: The HPS JTAG interface does not support boundary scan tests (BST). To perform boundary scan testing on HPS I/Os, use the FPGA JTAG pins.

Related Information

http://infocenter.arm.com/
For more information, refer to the *CoreSight Components* Technical Reference Manual on the ARM info center website.

System Trace Macrocell (STM)

The STM allows messages to be injected into the trace stream for delivery to the host debugger receiving the trace data. These messages can be sent via stimulus ports or the hardware event interface. The STM allows the messages to be time stamped.

The STM provides an AMBA Advanced eXtensible Interface (AXI™) slave interface used to create trace events. The interface can be accessed by the MPU subsystem, direct memory access (DMA) controller, and masters implemented as soft logic in the FPGA fabric via the FPGA-to-HPS bridge. The AXI slave interface supports three address segments, where each address segment is 16 MB and each segment supports up to 65536 channels. Each channel occupies 256 bytes of address space.

The STM also provides 32 hardware event pins. The higher-order 28 pins (31:4) are connected to the FPGA fabric, allowing logic inside FPGA to insert messages into the trace stream. When the STM detects a rising edge on an event pin, a message identifying the event is inserted into the stream. The lower four event pins (3:0) are connected to csCTI.

Related Information

- **HPS-FPGA Bridges** on page 8-1

- **http://infocenter.arm.com/**
  For more information, refer to the *CoreSight System Trace Macrocell* Technical Reference Manual on the ARM info center website.

Trace Funnel

The Trace Funnel multiplexes three trace sources into a single trace stream. Port 0 of the Trace Funnel is connected to the PTM for CPU 0. Port 1 of the Trace Funnel is connected to the PTM for CPU 1. Port 3 of the Trace Funnel is connected to the STM. Port 2 and Port 4 through Port 7 are not used.

Related Information

http://infocenter.arm.com/
For more information, refer to the *CoreSight Components* Technical Reference Manual on the ARM info center website.

Embedded Trace FIFO (ETF)

The output of the Trace Funnel is sent to the ETF. The ETF is used as an elastic buffer between trace generators (STM, PTM) and trace destinations. The ETF stores up to 32 KB of trace data in the on-chip trace RAM.

AMBA Trace Bus Replicator (Replicator)

The Replicator broadcasts trace data from the ETF to the embedded trace router (ETR) and trace port interface unit (TPIU).

Related Information

http://infocenter.arm.com/
For more information, refer to the *CoreSight Components* Technical Reference Manual on the ARM info center website.

Embedded Trace Router (ETR)

The ETR can route trace data to the HPS on-chip RAM, the HPS SDRAM, and any memory in the FPGA fabric connected to the HPS-to-FPGA bridge. The ETR receives trace data from the Replicator. By default, the buffer to receive the trace data resides in SDRAM at offset 0x00100000 and is 32 KB. You can override this default configuration by programming registers in the ETR.

Related Information

HPS-FPGA Bridges on page 8-1

Trace Port Interface Unit (TPIU)

The TPIU is a bridge between on-chip trace sources and an off-chip trace port. The TPIU receives trace data from the Replicator and drives the trace data to a trace port analyzer.

The trace output from the TPIU is software programmable and can be set to either 8 or 32 bits wide. The trace output is routed to an 8-bit HPS I/O interface and a 32-bit interface to the FPGA fabric. The trace data sent to the FPGA fabric can be transported off-chip using available serializer/deserializer (SERDES) resources in the FPGA.

Related Information

http://infocenter.arm.com/

For more information, refer to the *CoreSight Components* Technical Reference Manual on the ARM info center website.

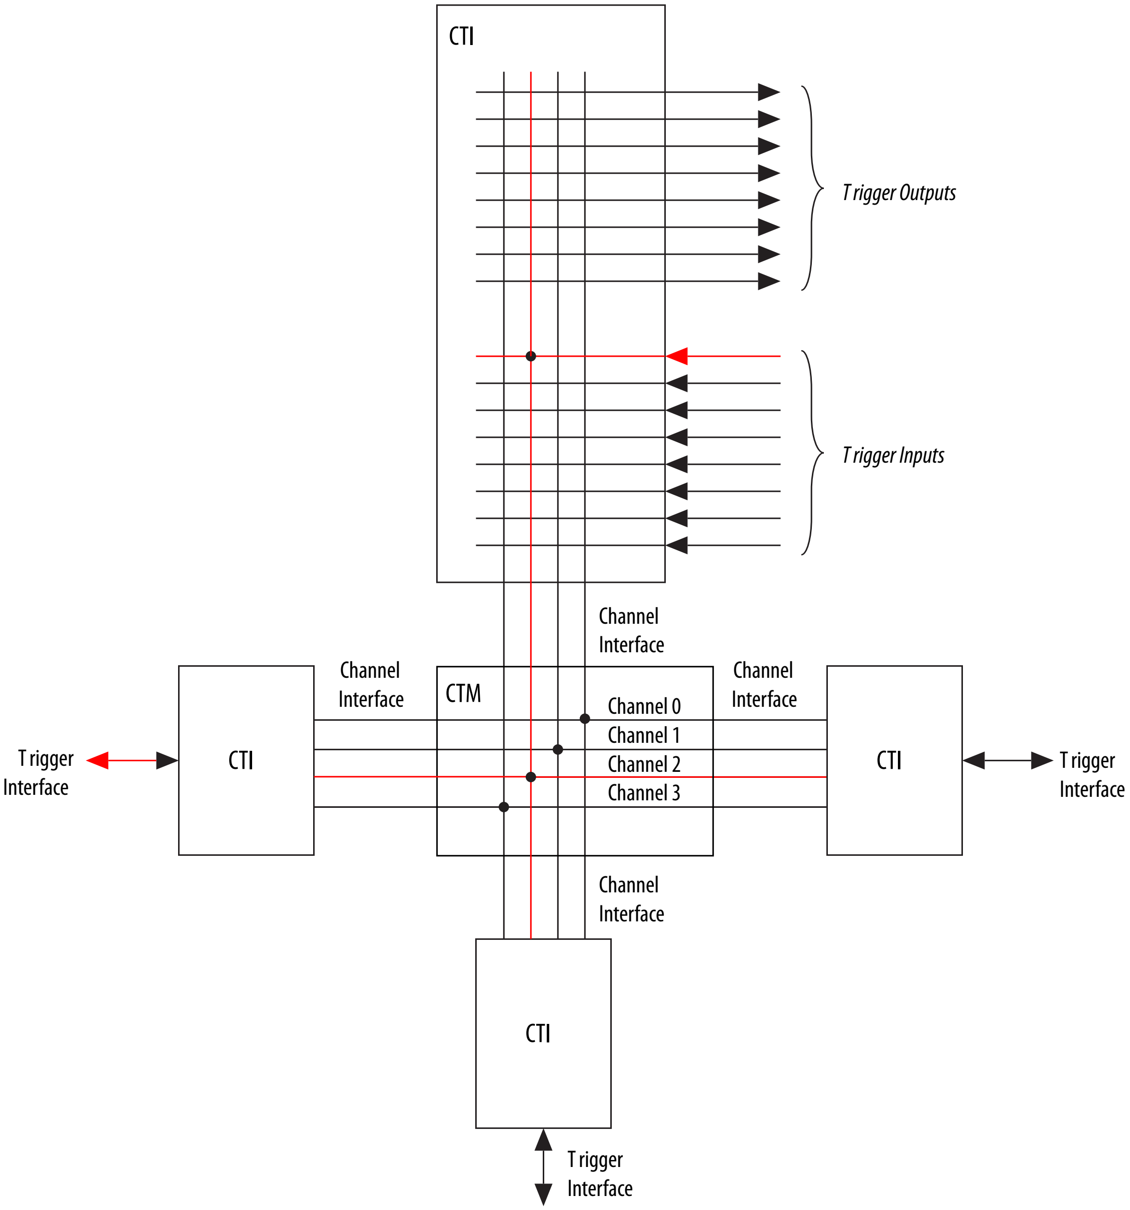
Embedded Cross Trigger (ECT) System

The ECT system provides a mechanism for HPS modules to trigger each other. The ECT consists of the following modules:

- Cross Trigger Interface (CTI)
- Cross Trigger Matrix (CTM)

Figure 10-2: Generic ECT System

The following figure shows how CTIs and CTMs are used in a generic ECT setup. The red line depicts an trigger input to one CTI generating a trigger output in another CTI. Though the signal travels throughout channel 2, it only enters and exits through trigger inputs and outputs you configure.



Related Information

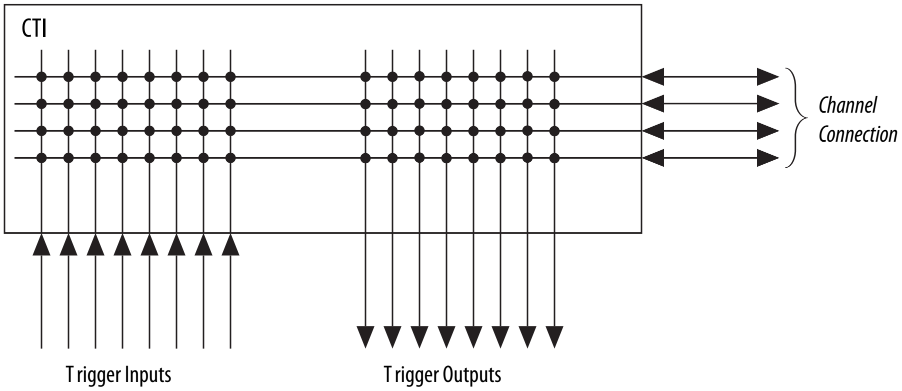
- Cross Trigger Interface (CTI) on page 10-8
- Cross Trigger Matrix (CTM) on page 10-8

Cross Trigger Interface (CTI)

CTIs allow trigger sources and sinks to interface with the ECT. Each CTI supports up to eight trigger inputs and eight trigger outputs, and is connected to a CTM. **Figure 10-2** shows the relationship of trigger inputs, trigger outputs, and CTM channels of a CTI.

Figure 10-3: CTI Connections

The following figure shows trigger input and trigger output connections in detail.



The HPS debug system contains the following four CTIs:

- csCTI—performs cross triggering between the STM, ETF, ETR, and TPIU.
- FPGA-CTI—exposes the cross-triggering system to the FPGA fabric.
- CTI-0 and CTI-1—reside in the MPU debug subsystem. Each CTI is associated with a processor and the processor's associated PTM.

Cross Trigger Matrix (CTM)

A CTM is a transport mechanism for triggers traveling from one CTI to one or more CTIs or CTMs. The HPS contains two CTMs. One CTM connects csCTI and FPGA-CTI; the other connects CTI-0 and CTI-1. The two CTMs are connected together, allowing triggers to be transmitted between the MPU debug subsystem, the debug system, and the FPGA fabric.

Each CTM has four ports and each port has four channels. Each CTM port can be connected to a CTI or another CTM.

Figure 10-4: CTM Channel Structure

The following figure shows the structure of a CTM channel. Paths inside the CTM are purely combinatorial.

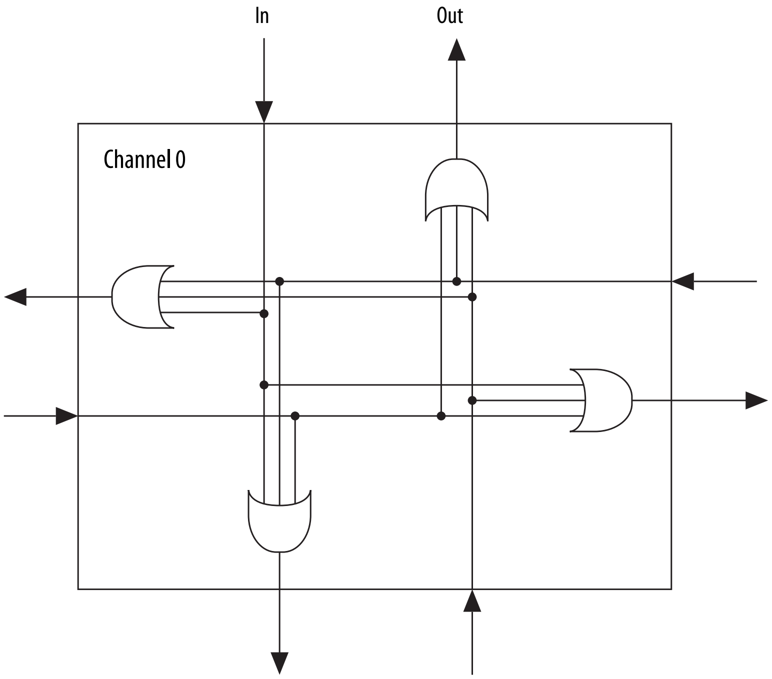


Figure 10-5: CTI Trigger Connections

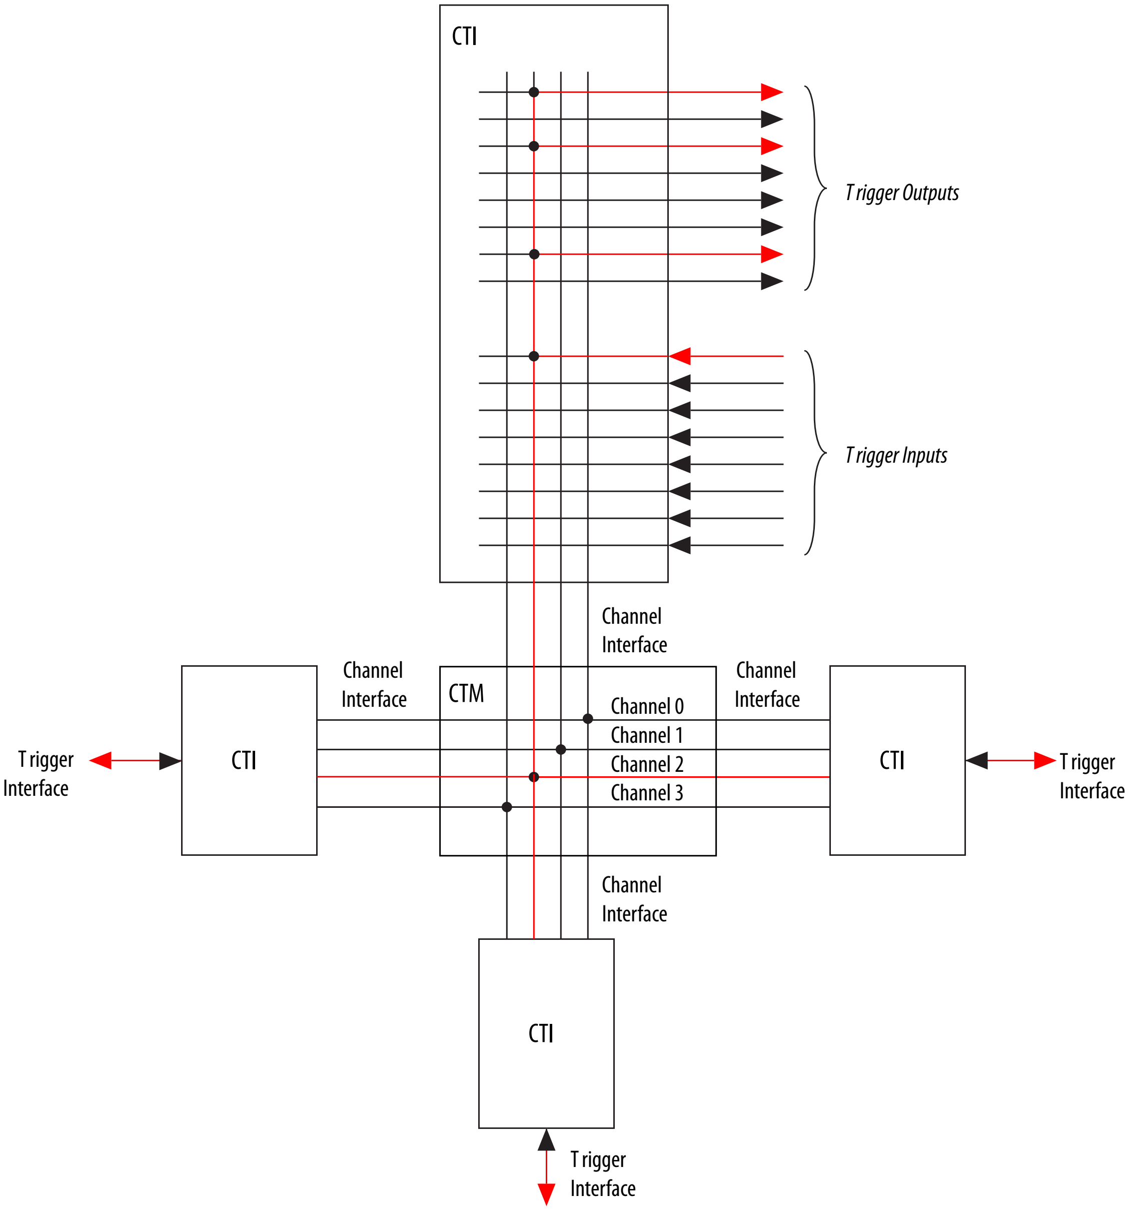
Each CTI trigger input can be connected through a CTM to one or more trigger outputs under control by a debugger. The following figure shows a pictorial representation of CTI trigger connections. The red lines depict the impact one trigger input can have on the entire system.



Related Information

http://infocenter.arm.com/

For more information, refer to the *CoreSight Components* Technical Reference Manual on the ARM info center website.

Program Trace Macrocell (PTM)

The PTM performs real-time program flow instruction tracing and provides a variety of filters and triggers that can be used to trace specific portions of code.

The HPS contains two PTMs. Each PTM is paired with a processor and CTI. Trace data generated from the PTM can be transmitted off-chip using HPS pins, or to the FPGA fabric, where it can be pre-processed and transmitted off-chip using high-speed FPGA pins.

Related Information

http://infocenter.arm.com/
For more information, refer to the *CoreSight PTM-A9* Technical Reference Manual.

HPS Debug APB Interface

The HPS can extend the CoreSight debug control bus into the FPGA fabric. The debug interface is an APB-compatible interface with built-in clock crossing.

Related Information

HPS Component Interfaces on page 28-1

CoreSight Debug and Trace Programming Model

This section describes programming model details specific to Altera's implementation of the ARM CoreSight technology.

The debug components can be configured to cause triggers when certain events occur. For example, soft logic in the FPGA fabric can signal an event which triggers an STM message injection into the trace stream. CoreSight components are configured through memory-mapped registers, located at offsets relative to the CoreSight component base address. CoreSight component base addresses are accessible through a ROM table.

Related Information

http://infocenter.arm.com/
Programming interface details of each CoreSight component.

ROM Table

Table 10-1: DAP ROM Table

The following table contains entries found in the ROM table portion of the DAP.

ROM Entry	Offset[30:12]	Description
0x0	0x00001	ETF
0x1	0x00002	CTI
0x2	0x00003	TPIU
0x3	0x00004	Trace Funnel

ROM Entry	Offset[30:12]	Description
0x4	0x00005	STM
0x5	0x00006	ETR
0x6	0x00007	FPGA-CTI
0x7	0x00100	A9ROM
0x8	0x00080	FPGAROM
0x9	0x00000	End of ROM

A host debugger can access this table at 0x8000_0000 through the DAP. HPS masters can access this ROM at 0xFF00_0000. Registers for a particular CoreSight component are accessed by adding the register offset to the CoreSight component base address, and adding that total to the base address of the ROM table.

The base address of the ROM table is different when accessed from the debugger (at 0x8000_0000) than when accessed from any HPS master (at 0xFF00_0000). For example, the CTI output enable register, `CTIOUTEN[2]` at offset 0xA8, can be accessed by the host debugger at 0x8000_20A8. To derive that value, add the host debugger access address to the ROM table of 0x8000_0000, to the CTI component base address of 0x0000_2000, to the `CTIOUTEN[2]` register offset of 0xA8.

STM Channels

The STM AXI slave is connected to the MPU, DMA, and FPGA-to-HPS bridge masters. Each master has up to 65536 channels where each channel occupies 256 bytes of address space, for a total of 16 MB per master. The HPS address map allocates 48 MB of consecutive address space to the STM AXI slave port, divided in three 16 MB segments.

Table 10-2: STM AXI Slave Port Address Allocation

Segment	Start Address	End Address
0	0xFC00_0000	0xFCFF_FFFF
1	0xFD00_0000	0xFDFF_FFFF
2	0xFE00_0000	0xFEFF_FFFF

Each of the three masters can access any one of the three address segments. Your software design determines which master uses which segment, based on the value of bits 24 and 25 in the write address, `AWADDRS[25:24]`. Software must restrict each master to use only one of the three segments.

Table 10-3: STM AXI Address Fields

AXI Signal Fields	Description
`AWADDRS[7:0]`	These bits index the 256 bytes of the stimulus port.

AXI Signal Fields	Description
`AWADDRS[23:8]`	These bits identify the 65536 stimulus ports associated with a master.
`AWADDRS[25:24]`	These bits identify the three masters. Only 0, 1, and 2 are valid values.
`AWADDRS[31:26]`	Always 0x3F. Bits 24 to 31 combine to access 0xFC00_0000 through 0xFEFF_FFFF.

Each STM message contains a master ID that tells the host debugger which master is associated with the message. The STM master ID is determined by combining a portion of the `AWADDRS` signal and the `AWPROT` protection bit.

Table 10-4: STM Master ID Calculation

Master ID Bits	AXI Signal Bits	Notes
Master ID[5:0]	`AWADDRS[29:24]`	The lowest two bits are sufficient to determine which master, but CoreSight uses a seven-bit master ID.
Master ID[6]	`AWPROT[1]`	0 indicates secure; 1 indicates nonsecure.

In addition to access through STM channels, the higher-order 28 (31:4) of the 32 event signals are attached to the FPGA through the FPGA-CTI. These event signals allow the FPGA fabric to send additional messages using the STM.

Related Information

FPGA Interface

The following components connect to the FPGA fabric. This section lists the signals from debug system to the FPGA.

DAP

The DAP uses the system APB port to connect to the FPGA.

Table 10-5: DAP

The following table shows the signal description between DAP and FPGA.

Segment	Description
h2f_dbg_apb_PADDR[18]	Address bus to system APB port

Segment	Description
h2f_dbg_apb_PADDR31	Address bus to system APB port
h2f_dbg_apb_PENABLE	Enable signal from system APB port
h2f_dbg_apb_PRDATA[32]	32-bit system APB port read data bus
h2f_dbg_apb_PREADY	Ready signal to system APB port
h2f_dbg_apb_PSEL	Select signal from system APB port
h2f_dbg_apb_PSLVERR	Error signal to system APB port
h2f_dbg_apb_PSLVERR	32-bit system APB port write data bus
h2f_dbg_apb_PWRITE	Select whether read or write to system APB port • 0 - System APB port read from DAP • 1 - System APB Port write to DAP

STM

The STM has 28 event pins, f2h_stm_hw_events[28], for FPGA to trigger events to STM.

FPGA-CTI

The FPGA-CTI allows the FPGA to send and receive triggers from the debug system.

Table 10-6: FPGA-CTI

The following table lists the signal descriptions between the FPGA-CTI and FPGA.

Signal	Description
h2f_cti_trig_in[8]	Trigger input from FPGA
h2f_cti_trig_in_ack[8]	ACK signal to FPGA
h2f_cti_trig_out[8]	Trigger output to FGPA
h2f_cti_trig_out_ack[8]	ACK signal from FPGA
h2f_cti_clk	Clock input from FPGA
h2f_cti_fpga_clk_en	Clock enable driven by FPGA
h2f_cti_asicctl[8]	Signal from FPGA

Related Information

http://infocenter.arm.com/

TPIU

Table 10-7: TPIU Signals

The following table lists the signal descriptions between the TPIU and FPGA.

Signal	Description
h2f_tpiu_clk_ctl	Selects whether trace data is captured using the internal TPIU clock or an external clock provided as an input to the TPIU from the FPGA. 0 - use h2f_tpiu_clock_in 1 - use internal clock Note: When the FPGA is powered down or not configured the TPIU uses the internal clock.
h2f_tpiu_data[32]	32 bit trace data bus to the FPGA. Trace data changes on both edges of h2f_tpiu_clock. Note: When the FPGA is powered down or not configured, the TPIU sends the lower 8-bits trace data to I/Os.
h2f_tpiu_clock_in	Clock from the FPGA used to capture trace data.
h2f_tpiu_clock	Clock output from TPIU

CTI Trigger Connections to Outside the Debug System

The following CTIs in the HPS debug system connect to outside the debug system:

- csCTI
- FPGA-CTI

csCTI

This section lists the trigger input, output, and output acknowledge pin connections implemented for csCTI in the debug system. The trigger input acknowledge signals are not connected to pins.

Table 10-8: csCTI Trigger Input Signals

The following table lists the trigger input pin connections implemented for csCTI.

Number	Signal	Source
7	ASYNCOUT	STM
6	TRIGOUTHETE	STM
5	TRIGOUTSW	STM
4	TRIGOUTSPTE	STM

Number	Signal	Source
3	ACQCOMP	ETR
2	FULL	ETR
1	ACQCOMP	ETF
0	FULL	ETF

Table 10-9: csCTI Trigger Output Signals

The following table lists the trigger output pin connections implemented for csCTI.

Number	Signal	Destination
7	TRIGIN	ETF
6	FLUSHIN	ETF
5	HWEVENTS[3:2]	STM
4	HWEVENTS[1:0]	STM
3	TRIGIN	TPIU
2	FLUSHIN	TPIU
1	TRIGIN	ETR
0	FLUSHIN	ETR

Table 10-10: csCTI Trigger Output Acknowledge Signals

The following table lists the trigger output pin acknowledge connections implemented for csCTI.

Number	Signal	Source
7	0	—
6	0	—
5	0	—
4	0	—
3	TRIGINACK	TPIU
2	FLUSHINACK	TPIU

Number	Signal	Source
1	0	—
0	0	—

FPGA-CTI

FPGA-CTI connects the debug system to the FPGA fabric. FPGA-CTI has all of its triggers available to the FPGA fabric.

Configuring Embedded Cross-Trigger Connections

CTI interfaces are programmable through a memory-mapped register interface.

The specific registers are described in the CoreSight Components Technical Reference Manual, which you can download from the ARM website (infocenter.arm.com).

To access registers in any CoreSight component through the debugger, the register offsets must be added to the CoreSight component's base address. That combined value must then be added to the address at which the ROM table is visible to the debugger (0x80000000).

Each CTI has two interfaces, the trigger interface and the channel interface. The trigger interface is the interface between the CTI and other components. It has eight trigger signals, which are hardwired to other components. The channel interface is the interface between a CTI and its CTM, with four bidirectional channels. The mapping of trigger interface to channel interface (and vice versa) in a CTI is dynamically configured. You can enable or disable each CTI trigger output and CTI trigger input connection individually.

For example, you can configure trigger input 0 in the FPGA-CTI to route to channel 3, and configure trigger output 3 in the FPGA-CTI and trigger output 7 in CTI-0 in the MPU debug subsystem to route from channel 3. This configuration causes a trigger at trigger input 0 in FPGA-CTI to propagate to trigger output 3 in the FPGA-CTI and trigger output 7 in CTI-0. Propagation can be single-to-single, single-to-multiple, multiple-to-single, and multiple-to-multiple.

A particular soft logic signal in the FPGA connected to a trigger input in the FPGA-CTI can be configured to trigger a flush of trace data to the TPIU. For example, you can configure channel 0 to trigger output 2 in csCTI. Then configure trigger input T3 to channel 0 in FPGA-CTI. Trace data is flushed to the TPIU when a trigger is received at trigger output 2 in csCTI.

Another soft logic signal in the FPGA connected to trigger input T2 in FPGA-CTI can be configured to trigger an STM message. csCTI output triggers 4 and 5 are wired to the STM CoreSight component in the HPS. For example, configure channel 1 to trigger output 4 in csCTI. Then configure trigger input T2 to channel 1 in FPGA-CTI.

Another soft logic signal in the FPGA fabric connected to trigger input T1 in FPGA-CTI can be configured to trigger a breakpoint on CPU 1. Trigger output 1 in CTI-1 is wired to the debug request (EDBGRQ) signal of CPU-1. For example, configure channel 2 to trigger output 1 in CTI-1. Then configure trigger input T1 to channel 2 in FPGA-CTI.

http://infocenter.arm.com/

Debug Clocks

The CoreSight system uses several different clocks. Port Name is the name of the clock signal inputs described for individual CoreSight debug components in the ARM documentation. Signal Name is the name of the clock signal used with other HPS components.

Table 10-11: CoreSight Clocks

Port Name	Clock Source	Signal Name	Description
ATCLK	Clock manager	dbg_at_clk	Trace bus clock.
CTICLK(for csCTI)	Clock manager	dbg_at_clk	Cross trigger interface clock for csCTI. It can be synchronous or asynchronous to CTMCLK.
CTICLK (for FPGA-CTI)	FPGA fabric	fpga_cti_clk	Cross trigger interface clock for FPGA-CTI.
CTICLK (for CTI-0 and CTI-1)	Clock manager	mpu_clk	Cross trigger interface clock for CTI-0 and CTI-1. It can be synchronous or asynchronous to CTMCLK.
CTMCLK(for csCTM)	Clock manager	dbg_clk	Cross trigger matrix clock for csCTM. It can be synchronous or asynchronous to CTICLK.
CTMCLK(for CTM)	Clock manager	mpu_clk	Cross trigger matrix clock for CTM. It can be synchronous or asynchronous to CTICLK.
DAPCLK	Clock manager	dbg_clk	DAP internal clock. It must be equivalent to PCLKDBG.
PCLKDBG	Clock manager	dbg_clk	Debug APB (DAPB) clock.
HCLK	Clock manager	dbg_clk	Used by the AHB-Lite master inside the DAP. It is asynchronous to DAPCLK. In the HPS, the AHB-Lite port uses same clock as DAPCLK.
PCLKSYS	Clock manager	l4_mp_clk	Used by the APB slave port inside the DAP. It is asynchronous to DAPCLK.

Port Name	Clock Source	Signal Name	Description
SWCLKTCK	JTAG interface	dap_tck	The SWJ-DP clock driven by the external debugger through either the JTAG interface or the FPGA fabric. It is asynchronous to DAPCLK. When through the JTAG interface, this clock is the same as TCK of the JTAG interface.
	FPGA fabric	tpiu_traceclkin	
TRACECLKIN	Clock manager	dbg_trace_clk	TPIU trace clock input. It is asynchronous to ATCLK. In the HPS, this clock can come from the clock manager or the FPGA fabric.

Related Information

http://infocenter.arm.com/
For more information about the CoreSight port names, refer to the *CoreSight Technology System* Design Guide, which you can download from the ARM info center website.

Debug Resets

The CoreSight system uses several resets. Port Name is the name of the clock signal inputs described for individual CoreSight debug components in the ARM documentation. Signal Name is the name of the clock signal used with other HPS components.

Table 10-12: CoreSight Resets

Port Name	Clock Source	Signal Name	Description
ATRESETn	Reset manager	dbg_rst_n	Trace bus reset. It resets all registers in ATCLK domain.
nCTIRESET	Reset manager	dbg_rst_n	CTI reset signal. It resets all registers in CTICLK domain. In the HPS, there are four instances of CTI. All four use the same reset signal.
DAPRESETn	Reset manager	dbg_rst_n	DAP internal reset. It is connected to PRESETDBGn.
PRESETDBGn	Reset manager	dbg_rst_n	Debug APB reset. Resets all registers clocked by PCLKDBG.
HRESETn	Reset manager	sys_dbg_rst_n	SoC-provided reset signal that resets all of the AMBA on-chip interconnect. Use this signal to reset the DAP AHB-Lite master port.
PRESETSYSn	Reset manager	sys_dbg_rst_n	Resets system APB slave port of DAP.

Port Name	Clock Source	Signal Name	Description
nCTMRESET	Reset manager	dbg_rst_n	CTM reset signal. It resets all signals clocked by CTMCLK.
nPOTRST	Reset manager	tap_cold_rst_n	True power on reset signal to the DAP SWJ-DP. It must only reset at power-on.
nTRST	JTAG interface	nTRST pin	Resets the DAP TAP controller inside the SWJ-DP. This signal is driven by the host using the JTAG connector.
TRESETn	Reset manager	dbg_rst_n	Reset signal for TPIU. Resets all registers in the TRACECLKIN domain.

The ETR stall enable field (etrstallen) of the ctrl register in the reset manager controls whether the ETR is requested to stall its AXI master interface to the L3 interconnect before a warm or debug reset.

The level 4 (L4) watchdog timers can be paused during debugging to prevent reset while the processor is stopped at a breakpoint.

Functional Description—HPS Memory Controller 11

2014.06.30

cv_54008 Subscribe Send Feedback

The hard processor system (HPS) SDRAM controller subsystem provides efficient access to external SDRAM for the ARM® Cortex™-A9 microprocessor unit (MPU) subsystem, the level 3 (L3) interconnect, and the FPGA fabric. The SDRAM controller provides an interface between the FPGA fabric and HPS. The interface accepts Advanced Microcontroller Bus Architecture (AMBA®) Advanced eXtensible Interface (AXI™) and Avalon® Memory-Mapped (Avalon-MM) transactions, converts those commands to the correct commands for the SDRAM, and manages the details of the SDRAM access.

Features of the SDRAM Controller Subsystem

The SDRAM controller subsystem offers programming flexibility, port and bus configurability, error correction, and power management for external memories up to 4 GB.

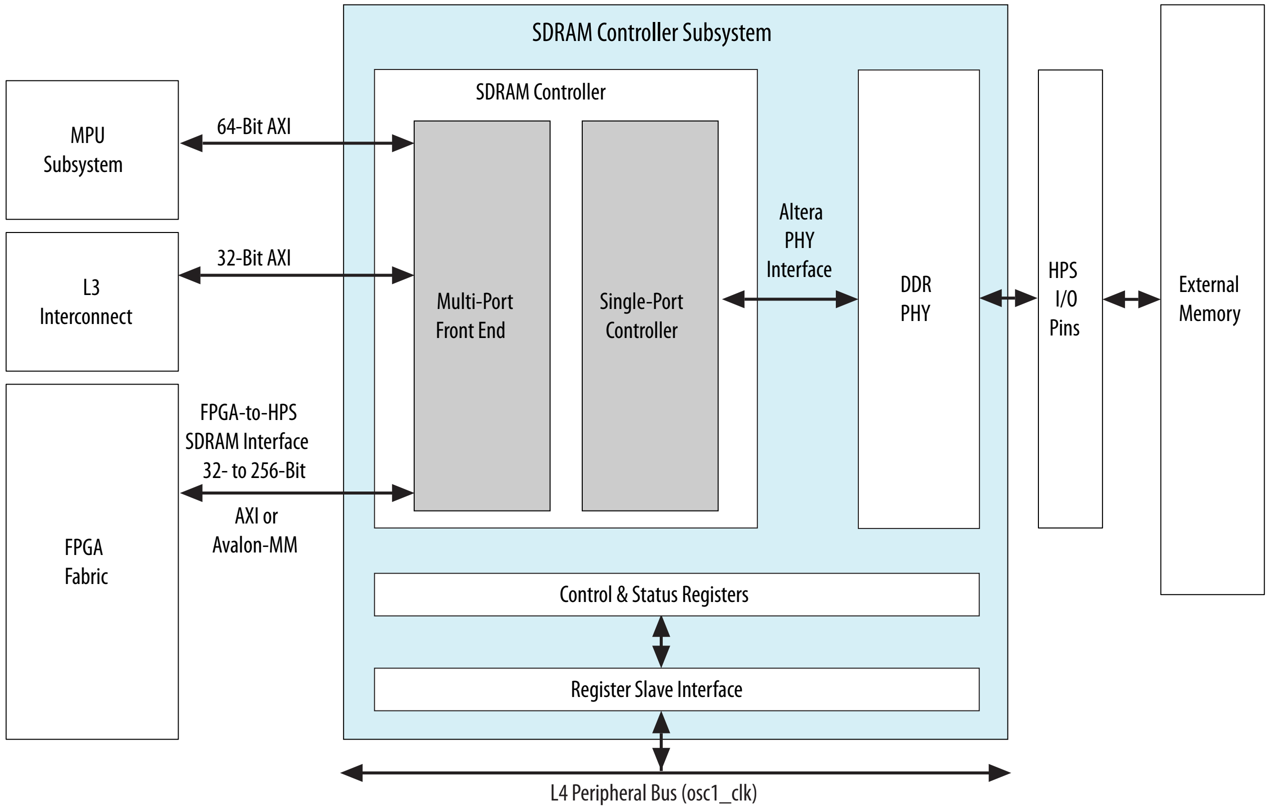
- Support for double data rate 2 (DDR2), DDR3, and low-power DDR2 (LPDDR2) SDRAM
- Flexible row and column addressing with the ability to support up to 4 GB of memory in various interface configurations
- Optional 8-bit integrated error correction code (ECC) for 16- and 32-bit data widths[16]
- User-configurable memory width of 8, 16, 16+ECC, 32, 32+ECC
- User-configurable timing parameters
- Two chip selects
- Command reordering (look-ahead bank management)
- Data reordering (out of order transactions)
- User-controllable bank policy on a per port basis for either closed page or conditional open page accesses
- User-configurable priority support with both absolute and weighted round-robin scheduling
- Flexible FPGA fabric interface with up to 6 ports that can be combined for a data width up to 256 bits wide using Avalon-MM and AXI interfaces.
- Power management supporting self refresh, partial array self refresh (PASR), power down, and LPDDR2 deep power down

[16] The level of ECC support is package dependent.

SDRAM Controller Subsystem Block Diagram

The SDRAM controller subsystem connects to the MPU subsystem, the main switch of the L3 interconnect, and the FPGA fabric. The memory interface consists of the SDRAM controller, the physical layer (PHY), control and status registers (CSRs), and their associated interfaces.

Figure 11-1: SDRAM Controller Subsystem High-Level Block Diagram



SDRAM Controller

The SDRAM controller provides high performance data access and run-time programmability. The controller reorders data to reduce row conflicts and bus turn-around time by grouping read and write transactions together, allowing for efficient traffic patterns and reduced latency.

The SDRAM controller consists of a multiport front end (MPFE) and a single-port controller. The MPFE provides multiple independent interfaces to the single-port controller. The single-port controller communicates with and manages each external memory device.

The MPFE FPGA-to-HPS SDRAM interface port has an asynchronous FIFO buffer followed by a synchronous FIFO buffer. Both the asynchronous and synchronous FIFO buffers have a read and write data FIFO depth of 8, and a command FIFO depth of 4. The MPU sub-system 64-bit AXI and L3 interconnect 32-bit AXI have asynchronous FIFO buffers with read and write data FIFO depth of 8, and command FIFO depth of 4.

DDR PHY

The DDR PHY provides a physical layer interface for read and write memory operations between the memory controller and memory devices. The DDR PHY has dataflow components, control components, and calibration logic that handle the calibration for the SDRAM interface timing.

	1024 (1 Gb) - S4 [19]	11	3	13	128	2048
	2048 (2 Gb) - S2 [18]	11	2	15	256	2048
	2048 (2 Gb) -S4 [19]	11	3	14	256	2048
	4096 (4 Gb)	12	3	14	512	4096

SDRAM Controller Subsystem Interfaces

MPU Subsystem Interface

The SDRAM controller connects to the MPU subsystem with a dedicated 64-bit AXI interface, operating on the `mpu_l2_ram_clk` clock domain.

L3 Interconnect Interface

The SDRAM controller interfaces to the L3 interconnect with a dedicated 32-bit AXI interface, operating on the `l3_main_clk` clock domain.

Related Information

System Interconnect on page 7-1

[17] For all memory types shown in this table, the DQ width is 8.

[18] S2 signifies a 2n prefetch size

[19] S4 signifies a 4n prefetch size

CSR Interface

The CSR interface connects to the level 4 (L4) bus and operates on the `l4_sp_clk` clock domain. The MPU subsystem uses the CSR interface to configure the controller and PHY, for example, setting the memory timing parameter values or placing the memory to a low power state. The CSR interface also provides access to the status registers in the controller and PHY.

FPGA-to-HPS SDRAM Interface

The FPGA-to-HPS SDRAM interface provides masters implemented in the FPGA fabric access to the SDRAM controller subsystem in the HPS. The interface has three ports types that are used to construct the following AXI or Avalon-MM interfaces:

- Command ports—issue read and/or write commands, and for receive write acknowledge responses
- 64-bit read data ports—receive data returned from a memory read
- 64-bit write data ports—transmit write data

The FPGA-to-HPS SDRAM interface supports six command ports, allowing up to six Avalon-MM interfaces or three AXI interfaces. Each command port can be used to implement either a read or write command port for AXI, or be used as part of an Avalon-MM interface. The AXI and Avalon-MM interfaces can be configured to support 32-, 64-, 128-, and 256-bit data.

Table 11-2: FPGA-to-HPS SDRAM Controller Port Types

Port Type	Available Number of Ports
Command	6
64-bit read data	4
64-bit write data	4

The FPGA-to-HPS SDRAM controller interface can be configured with the following characteristics:

- Avalon-MM interfaces and AXI interfaces can be mixed and matched as required by the fabric logic, within the bounds of the number of ports provided to the fabric.
- Because the AXI protocol allows simultaneous read and write commands to be issued, two SDRAM control ports are required to form an AXI interface.
- Because the data ports are natively 64-bit, they must be combined if wider data paths are required for the interface.
- Each Avalon-MM or AXI interface of the FPGA-to-HPS SDRAM interface operates on an independent clock domain.
- The FPGA-to-HPS SDRAM interfaces are configured during FPGA configuration.

The following table shows the number of ports needed to configure different bus protocols, based on type and data width.

Table 11-3: FPGA-to-HPS SDRAM Port Utilization

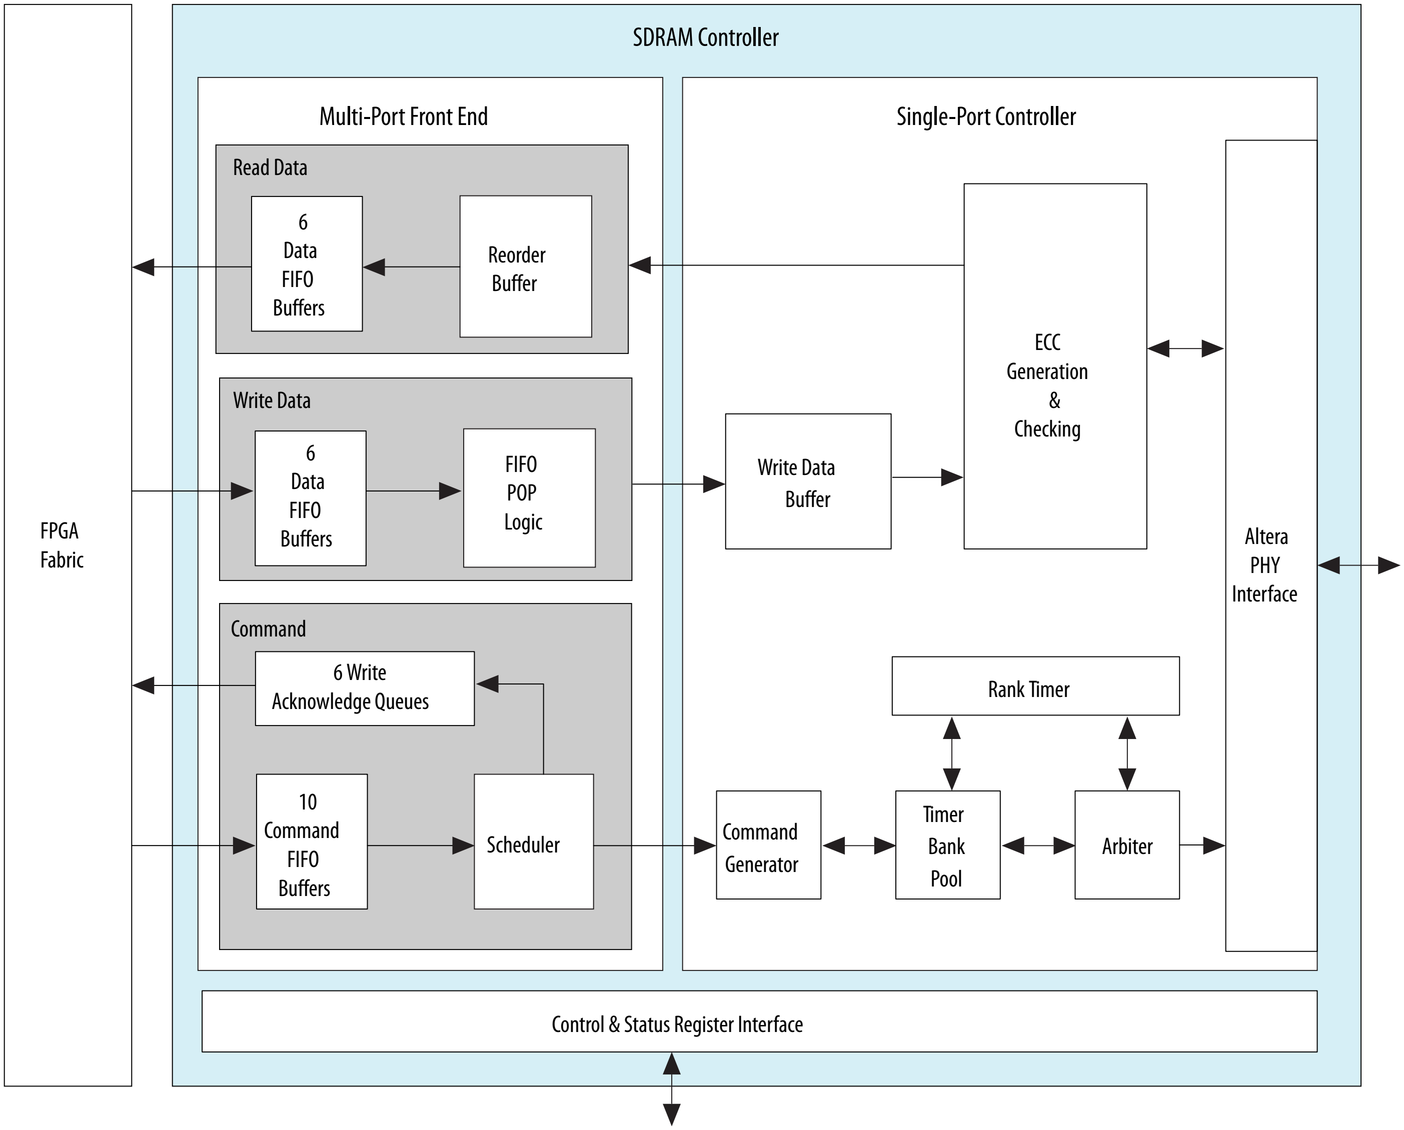
Bus Protocol	Command Ports	Read Data Ports	Write Data Ports
32- or 64-bit AXI	2	1	1

Bus Protocol	Command Ports	Read Data Ports	Write Data Ports
128-bit AXI	2	2	2
256-bit AXI	2	4	4
32- or 64-bit Avalon-MM	1	1	1
128-bit Avalon-MM	1	2	2
256-bit Avalon-MM	1	4	4
32- or 64-bit Avalon-MM write-only	1	0	1
128-bit Avalon-MM write-only	1	0	2
256-bit Avalon-MM write-only	1	0	4
32- or 64-bit Avalon-MM read-only	1	1	0
128-bit Avalon-MM read-only	1	2	0
256-bit Avalon-MM read-only	1	4	0

Memory Controller Architecture

The SDRAM controller consists of an MPFE, a single-port controller, and an interface to the CSRs.

Figure 11-2: SDRAM Controller Block Diagram



Multi-Port Front End

The Multi-Port Front End (MPFE) is responsible for scheduling pending transactions from the configured interfaces and sending the scheduled memory transactions to the single-port controller. The MPFE handles all functions related to individual ports.

The MPFE consists of three primary sub-blocks.

Command Block

The command block accepts read and write transactions from the FPGA fabric and the HPS. When the command FIFO buffer is full, the command block applies backpressure by deasserting the ready signal. For each pending transaction, the command block calculates the next SDRAM burst needed to progress on that transaction. The command block schedules pending SDRAM burst commands based on the user-supplied configuration, available write data, and unallocated read data space.

Write Data Block

The write data block transmits data to the single-port controller. The write data block maintains write data FIFO buffers and clock boundary crossing for the write data. The write data block informs the command block of the amount of pending write data for each transaction so that the command block can calculate eligibility for the next SDRAM write burst.

Read Data Block

The read data block receives data from the single-port controller. Depending on the port state, the read data block either buffers the data in its internal buffer or passes the data straight to the clock boundary crossing FIFO buffer. The read data block reorders out-of-order data for Avalon-MM ports.

In order to prevent the read FIFO buffer from overflowing, the read data block informs the command block of the available buffer area so the command block can pace read transaction dispatch.

Single-Port Controller

The single-port logic is responsible for following actions:

- Queuing the pending SDRAM bursts
- Choosing the most efficient burst to send next
- Keeping the SDRAM pipeline full
- Ensuring all SDRAM timing parameters are met

Transactions passed to the single-port logic for a single page in SDRAM are guaranteed to be executed in order, but transactions can be reordered between pages. Each SDRAM burst read or write is converted to the appropriate Altera PHY interface (AFI) command to open a bank on the correct row for the transaction (if required), execute the read or write command, and precharge the bank (if required).

The single-port logic implements command reordering (looking ahead at the command sequence to see which banks can be put into the correct state to allow a read or write command to be executed) and data reordering (allowing data transactions to be dispatched even if the data transactions are executed in an order different than they were received from the multi-port logic).

The single-port controller consists of eight sub-modules.

Command Generator

The command generator accepts commands from the MPFE and from the internal ECC logic, and provides those commands to the timer bank pool.

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

Timer Bank Pool

The timer bank pool is a parallel queue that operates with the arbiter to enable data reordering. The timer bank pool tracks incoming requests, ensures that all timing requirements are met, and, on receiving write-data-ready notifications from the write data buffer, passes the requests to the arbiter

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

Arbiter

The arbiter determines the order in which requests are passed to the memory device. When the arbiter receives a single request, that request is passed immediately. When multiple requests are received, the arbiter uses arbitration rules to determine the order to pass requests to the memory device.

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

Rank Timer

The rank timer performs the following functions:

- Maintains rank-specific timing information
- Ensures that only four activates occur within a specified timing window
- Manages the read-to-write and write-to-read bus turnaround time
- Manages the time-to-activate delay between different banks

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

Write Data Buffer

The write data buffer receives write data from the MPFE and passes the data to the PHY, on approval of the write request.

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

ECC Block

The ECC block consists of an encoder and a decoder-corrector, which can detect and correct single-bit errors, and detect double-bit errors. The ECC block can correct single- bit errors and detect double-bit errors resulting from noise or other impairments during data transmission.

Note: The level of ECC support is package dependent.

Related Information

- Memory Controller Architecture on page 11-6
  For more information, refer to the SDRAM Controller Block diagram.
- **http://www.altera.com/literature/hb/cyclone-v/cv_52006.pdf**

AFI Interface

The AFI interface provides communication between the controller and the PHY.

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

CSR Interface

The CSR interface is accessible from the L4 bus. The interface allows code executing in the HPS MPU and FPGA fabric to configure and monitor the SDRAM controller.

Related Information

Memory Controller Architecture on page 11-6
For more information, refer to the SDRAM Controller Block diagram.

Functional Description of the SDRAM Controller Subsystem

MPFE Operation Ordering

Operation ordering is defined and enforced within a port, but not between ports. All transactions received on a single port for overlapping addresses execute in order. Requests arriving at different ports have no guaranteed order of service, except when a first transaction has completed before the second arrives.

Avalon-MM does not support write acknowledgement. When a port is configured to support Avalon-MM, you should read from the location that was previously written to ensure that the write operation has completed. When a port is configured to support AXI, the master accessing the port can safely issue a read operation to the same address as a write operation as soon as the write has been acknowledged. To keep write latency low, writes are acknowledged as soon as the transaction order is guaranteed—meaning that any operations received on any port to the same address as the write operation are executed after the write operation.

To reduce read latency, the single-port logic can return read data out of order to the multi-port logic. The returned data is rearranged to its initial order on a per port basis by the multi-port logic and no traffic reordering occurs between individual ports.

Read Data Handling

The MPFE contains a read buffer shared by all ports. If a port is capable of receiving returned data then the read buffer is bypassed. If the size of a read transaction is smaller than twice the memory interface width, the buffer RAM cannot be bypassed. The lowest memory latency occurs when the port is ready to receive data and the full width of the interface is utilized.

MPFE Multi-port Scheduling

Multi-port scheduling is governed by two factors: the absolute priority of a transaction and the weighting of a port.

The evaluation of absolute priority ensures that ports carrying higher-priority traffic are served ahead of ports carrying lower-priority traffic. The scheduler recognizes eight priority levels (0-7), with higher values representing higher priorities. For example, any transaction with priority seven is scheduled before transactions of priority six or lower. The absolute priority for each port is configured by programming the `userpriority` field of the `mppriority` register.

When ports carry traffic of the same absolute priority, relative priority is determined based on port weighting. The static weight of a port and the sum of static weights are configured by programming the `mpweight_*_*` registers. Port weighting is a five-bit value (0-31), and is determined by a deficit-weighted round robin (DWRR) algorithm, which corrects for past over-servicing or under-servicing of a port. Each port has an associated weight which is updated every cycle, with a user-configured weight added to it and the amount of traffic served subtracted from it. The port with the highest weighting is considered the most eligible.

To ensure that high-priority traffic is served quickly and that long and short bursts are effectively interleaved between ports, incoming transactions longer than a single SDRAM burst are scheduled as a series of SDRAM bursts, with each burst arbitrated separately.

To ensure that lower priority ports do not build up large running weights while higher priority ports monopolize bandwidth, the controller's DWRR weights are updated only when a port matches the scheduled priority. Therefore, if three ports are being accessed, two being priority seven and one being priority four, the weights for both ports at priority seven are updated but the port with priority four remains unchanged.

Multi-port scheduling is performed between all of the ports connected to the FPGA fabric and internally in the HPS to determine which transaction is serviced next. Arbitration is performed on a SDRAM burst basis to ensure that a long transaction does not lock other transactions or cause latency to significantly increase for high-priority ports.

Arbitration supports both absolute and relative priority. Absolute priority is intended for applications where one master should always get priority above or below others. Relative priority is supported through a programmable weight field which controls scheduling between ports at the same priority.

The scheduler is work-conserving. Write operations can only be scheduled when enough data for the SDRAM burst has been received. Read operations can only be scheduled when sufficient internal memory is free and the port is not occupying too much of the read buffer.

The multi-port scheduling configuration can be updated while transactions are still active in the memory controller. Both priority and weight for a port can be updated without interrupting traffic on a port. Updates are used in scheduling decisions within 10 memory clock cycles of being updated, so priority can be updated frequently if needed. Multi-port priority is programmed in the `mppriority` register and port weight is configured in the `mpweight_*_*` registers.

Note: In addition to the `mppriority` register and `mpweight_*_*` registers, the `remappriority` register adds another level of priority to the port scheduling. By programming bit N in the `priorityremap` field of the `remappriority` register, any port with an absolute priority N is sent to the front of the single port command queue and is serviced before any other transaction. Please refer to the `remappriority` register for more details.

MPFE SDRAM Burst Scheduling

SDRAM burst scheduling recognizes addresses that access the same row/bank combination, known as open page accesses. Operations to a page are served in the order in which they are received by the single-port controller. Selection of SDRAM operations is a two-stage process. First, each pending transaction must wait for its timers to be eligible for execution. Next, the transaction arbitrates against other transactions that are also eligible for execution.

The following rules govern transaction arbitration:

- High-priority operations take precedence over lower-priority operations
- If multiple operations are in arbitration, read operations have precedence over write operations
- If multiple operations still exist, the oldest is served first

A high-priority transaction in the SDRAM burst scheduler wins arbitration for that bank immediately if the bank is idle and the high-priority transaction's chip select, row, or column fields of the address do not match an address already in the single-port controller. If the bank is not idle, other operations to that bank yield until the high-priority operation is finished. If the chip select, row, and column fields match an earlier transaction, the high-priority transaction yields until the earlier transaction is completed.

Clocking

The FPGA fabric ports of the MPFE can be clocked at different frequencies. Synchronization is maintained by clock-domain crossing logic in the MPFE. Command ports can operate on different clock domains, but the data ports associated with a given command port must be attached to the same clock as that command port.

Note: A command port paired with a read and write port to form an Avalon-MM interface must operate at the same clock frequency as the data ports associated with it.

Single-Port Controller Operation

The single-port controller increases the performance of memory transactions through command and data re-ordering, enforcing bank policies, combining write operations and allowing burst transfers. Correction of single-bit errors and detection of double-bit errors is handled in the ECC module of the single-port Controller.

SDRAM Interface

The SDRAM interface is up to 40 bits wide and can accommodate 8-bit, 16-bit, 16-bit plus ECC, 32-bit, or 32-bit plus ECC configurations, depending on the device package. The SDRAM interface supports LPDDR2, DDR2, and DDR3 memory protocols.

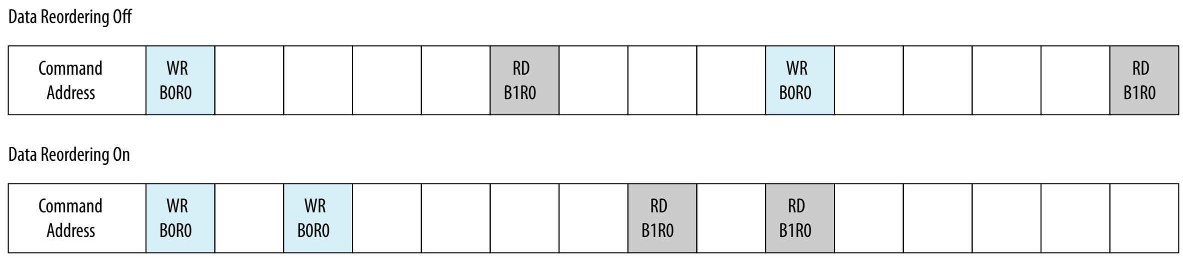
Command and Data Reordering

The heart of the SDRAM controller is a command and data reordering engine. Command reordering allows banks for future transactions to be opened before the current transaction finishes.

Data reordering allows transactions to be serviced in a different order than they were received when that new order allows for improved utilization of the SDRAM bandwidth. Operations to the same bank and row are performed in order to ensure that operations which impact the same address preserve the data integrity.

The following figure shows the relative timing for a write/read/write/read command sequence performed in order and then the same command sequence performed with data reordering. Data reordering allows the write and read operations to occur in bursts, without bus turnaround timing delay or bank reassignment.

Figure 11-3: Data Reordering Effect



Data Reordering Off

Command Address	WR B0R0					RD B1R0				WR B0R0					RD B1R0

Data Reordering On

Command Address	WR B0R0		WR B0R0					RD B1R0		RD B1R0					

The SDRAM controller schedules among all pending row and column commands every clock cycle.

Bank Policy

The bank policy of the SDRAM controller allows users to request that a transaction's bank remain open after an operation has finished so that future accesses do not delay in activating the same bank and row combination. The controller supports only eight simultaneously-opened banks, so an open bank might get closed if the bank resource is needed for other operations.

Open bank resources are allocated dynamically as SDRAM burst transactions are scheduled. Bank allocation is requested automatically by the controller when an incoming transaction spans multiple SDRAM bursts or by the extended command interface. When a bank must be reallocated, the least-recently-used open bank is used as the replacement.

If the controller determines that the next pending command will cause the bank request to not be honored, the bank might be held open or closed depending on the pending operation. A request to close a bank with a pending operation in the timer bank pool to the same row address causes the bank to remain open. A request to leave a bank open with a pending command to the same bank but a different row address causes a precharge operation to occur.

Write Combining

The SDRAM controller combines write operations from successive bursts on a port where the starting address of the second burst is one greater than the ending address of the first burst and the resulting burst length does not overflow the 11-bit burst-length counters.

Write combining does not occur if the previous bus command has finished execution before the new command has been received.

Burst Length Support

The controller supports burst lengths of 2, 4, 8, and 16, and data widths of 8, 16, and 32 bits for non-ECC operation, and widths of 24 and 40 operations with ECC enabled. The following table shows the type of SDRAM for each burst length.

Table 11-4: SDRAM Burst Lengths

Burst Length	SDRAM
4	LPDDR2, DDR2
8	DDR2, DDR3, LPDDR2
16	LPDDR2

Width Matching

The SDRAM controller automatically performs data width conversion.

ECC

The single-port controller supports memory ECC calculated by the controller.
The controller ECC employs standard Hamming logic to detect and correct single-bit errors and detect double-bit errors. The controller ECC is available for 16-bit and 32-bit widths, each requiring an additional 8 bits of memory, resulting in an actual memory width of 24-bits and 40-bits, respectively.

Note: The level of ECC support is package dependent.

Functions the controller ECC provides are:

- Byte Writes
- ECC Write Backs
- Notification of ECC Errors

Byte Writes

The memory controller performs a read-modify-write operation to ensure that the ECC data remains valid when a subset of the bits of a word is being written.

Byte writes with ECC enabled are executed as a read-modify-write. Typical operations only use a single entry in the timer bank pool. Controller ECC enabled sub-word writes use two entries. The first operation is a read and the second operation is a write. These two operations are transferred to the timer bank pool with an address dependency so that the write cannot be performed until the read data has returned. This approach ensures that any subsequent operations to the same address (from the same port) are executed after the write operation, because they are ordered on the row list after the write operation.

If an entire word is being written (but less than a full burst) and the DM pins are connected, no read is necessary and only that word is updated. If controller ECC is disabled, byte-writes have no performance impact.

ECC Write Backs

If the controller ECC is enabled and a read operation results in a correctable ECC error, the controller corrects the location in memory, if write backs are enabled. The correction results in scheduling a new read-modify-write.

A new read is performed at the location to ensure that a write operation modifying the location is not overwritten. The actual ECC correction operation is performed as a read-modify-write operation. ECC write backs are enabled and disabled through the `cfg_enable_ecc_code_overwrites` field in the `ctrlcfg` register.

User Notification of ECC Errors

When an ECC error occurs, an interrupt signal notifies the MPU subsystem, and the ECC error information is stored in the status registers. The memory controller provides interrupts for single-bit and double-bit errors.

The status of interrupts and errors are recorded in status registers, as follows:

- The `dramsts` register records interrupt status.
- The `dramintr` register records interrupt masks.
- The `sbecount` register records the single-bit error count.
- The `dbecount` register records the double-bit error count.
- The `erraddr` register records the address of the most recent error.

Interleaving Options

The controller supports the following address-interleaving options:

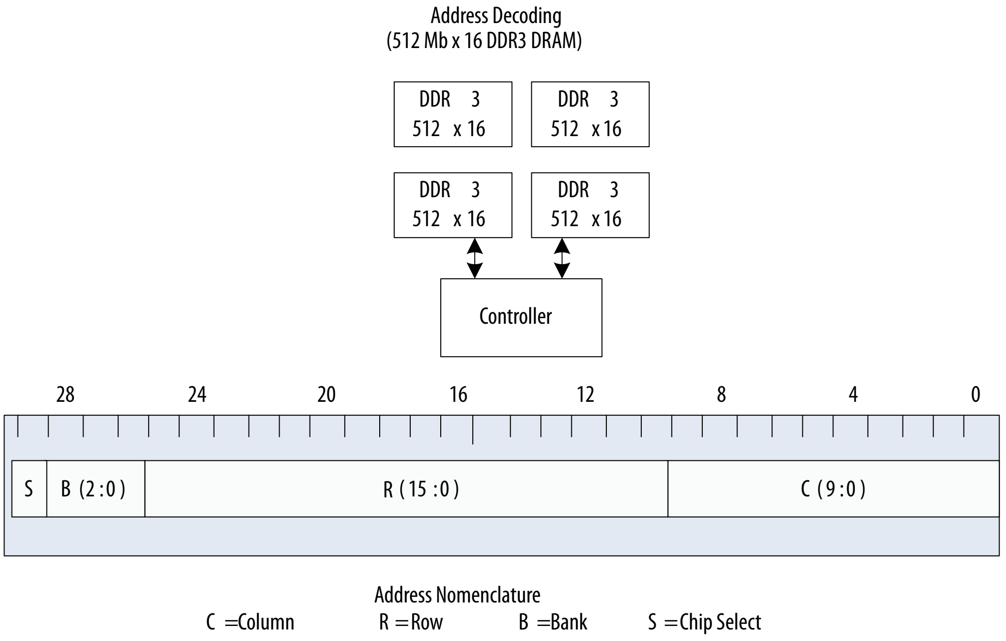
- Non-interleaved
- Bank interleave without chip select interleave
- Bank interleave with chip select interleave

The following interleaving examples use 512 megabits (Mb) x 16 DDR3 chips and are documented as byte addresses. For RAMs with smaller address fields, the order of the fields stays the same but the widths may change.

Non-interleaved

RAM mapping is non-interleaved.

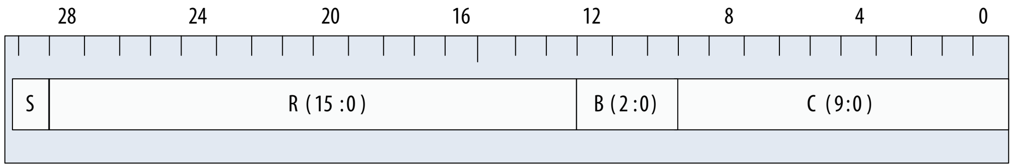
Figure 11-4: Non-interleaved Address Decoding



Bank Interleave Without Chip Select Interleave

Bank interleave without chip select interleave swaps row and bank from the non-interleaved address mapping. This interleaving allows smaller data structures to spread across all banks in a chip.

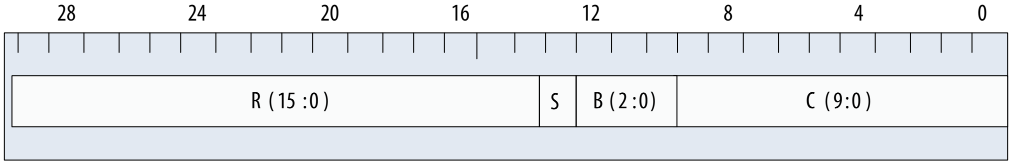
Figure 11-5: Bank Interleave Without Chip Select Interleave Address Decoding



Bank Interleave with Chip Select Interleave

Bank interleave with chip select interleave moves the row address to the top, followed by chip select, then bank, and finally column address. This interleaving allows smaller data structures to spread across multiple banks and chips (giving access to 16 total banks for multithreaded access to blocks of memory). Memory timing is degraded when switching between chips.

Figure 11-6: Bank Interleave With Chip Select Interleave Address Decoding



AXI-Exclusive Support

The single-port controller supports AXI-exclusive operations. The controller implements a table shared across all masters, which can store up to 16 pending writes. Table entries are allocated on an exclusive read and table entries are deallocated on a successful write to the same address by any master.

Any exclusive write operation that is not present in the table returns an exclusive fail as acknowledgement to the operation. If the table is full when the exclusive read is performed, the table replaces a random entry.

Note: When using AXI-exclusive operations, accessing the same location from Avalon-MM interfaces can result in unpredictable results.

Memory Protection

The single-port controller has address protection to allow the software to configure basic protection of memory from all masters in the system. If the system has been designed exclusively with AMBA masters, TrustZone® is supported. Ports that use Avalon-MM can be configured for port level protection.

Memory protection is based on physical addresses in memory. The single-port controller can configure up to 20 rules to allow or prevent masters from accessing a range of memory based on their AxIDs, level of security and the memory region being accessed. If no rules are matched in an access, then default settings take effect.

The rules are stored in an internal protection table and can be accessed through indirect addressing offsets in the `protruledwr` register in the CSR. To read a specific rule, set the `readrule` bit and write the appropriate offset in the `ruleoffset` field of the `protruledwr` register.

To write a new rule, three registers in the CSR must be configured:

1. The `protportdefault` register is programmed to control the default behavior of memory accesses when no rules match. When a bit is clear, all default accesses from that port pass. When a bit is set, all default accesses from that port fails. The bits are assigned as follows:

Table 11-5: `protportdefault` register

Bits	Description
`31:10`	reserved
`9`	When this bit is set to 1, deny CPU writes during a default transaction. When this bit is clear, allow CPU writes during a default transaction.

Bits	Description
8	When this bit is set to 1, deny L3 writes during a default transaction. When this bit is clear, allow L3 writes during a default transaction.
7	When this bit is set to 1, deny CPU reads during a default transaction. When this bit is clear, allow CPU reads during a default transaction.
6	When this bit is set to 1, deny L3 reads during a default transaction. When this bit is clear, allow L3 reads during a default transaction.
5:0	When this bit is set to 1, deny accesses from FPGA-to-SDRAM ports 0 through 5 during a default transaction. When this bit is clear, allow accesses from FPGA-to-SDRAM ports 0 through 5 during a default transaction.

2. The `protruleid` register gives the bounds of the AxID value that allows an access
3. The `protruledata` register configures the specific security characteristics for a rule.

Once the registers are configured, they can be committed to the internal protection table by programming the `ruleoffset` field and setting the `writerule` bit in the `protruledwr` register.

Secure and non-secure regions are specified by rules containing a starting address and ending address with 1 MB boundaries for both addresses. You can override the port defaults and allow or disallow all transactions.

The following table lists the fields that you can specify for each rule.

Table 11-6: Fields for Rules in Memory Protection Table

Field	Width	Description
Valid	1	Set to 1 to activate the rule. Set to 0 to deactivate the rule.
Port Mask [20]	10	Specifies the set of ports to which the rule applies, with one bit representing each port, as follows: bits 0 to 5 correspond to FPGA fabric ports 0 to 5, bit 6 corresponds to AXI L3 switch read, bit 7 is the CPU read, bit 8 is L3 switch write, and bit 9 is the CPU write.

[20] Although AxID and Port Mask could be redundant, including both in the table allows possible compression of rules. If masters connected to a port do not have contiguous AxIDs, a port-based rule might be more efficient than an AxID-based rule, in terms of the number of rules needed.

Field	Width	Description
AxID_ low[20]	12	Low transfer AxID of the rules to which this rule applies. Incoming transactions match if they are greater than or equal to this value. Ports with smaller AxIDs have the AxID shifted to the lower bits and zero padded at the top.
AxID_ high [20]	12	High transfer AxID of the rules to which this rule applies. Incoming transactions match if they are less than or equal to this value.
Address_ low	12	Points to a 1MB block and is the lower address. Incoming addresses match if they are greater than or equal to this value.
Address_ high	12	Upper limit of address. Incoming addresses match if they are less than or equal to this value.
Protection	2	A value of 0x0 indicates that the protection bit is not set; a value of 0x1 sets the protection bit. Values 0x2 and 0x3 set the region to shared, meaning both secure and non-secure accesses are valid.
Fail/allow	1	Set this value to 1 to force the operation to fail or succeed.

A port has a default access status of either allow or fail, and rules with the opposite allow/fail value can override the default. The system evaluates each transaction against every rule in the memory protection table. A transaction received on a port which by default allows access, would fail only if a rule with the fail bit matches the transaction. Conversely, a port which by default prevents access, would allow access only if a rule allows that transaction to pass.

Exclusive transactions are security checked on the read operation only. A write operation can occur only if a valid read is marked in the internal exclusive table. Consequently, a master performing an exclusive read followed by a write, can write to memory only if the exclusive read was successful.

Related Information

ARM TrustZone

For more information about TrustZone refer to the ARM web page.

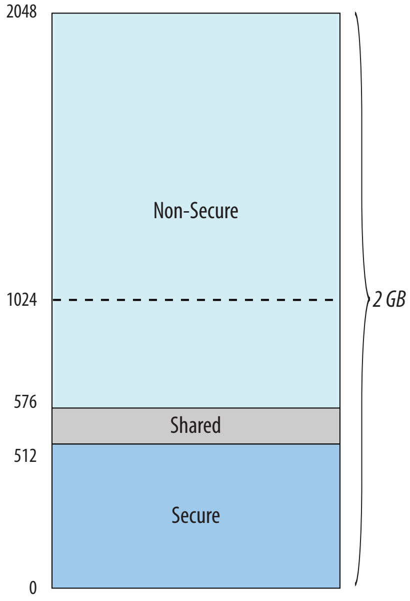
Example of Configuration for TrustZone

For a TrustZone configuration, memory isTrustZone divided into a range of memory accessible by secure masters and a range of memory accessible by non-secure masters. The two memory address ranges may have a range of memory that overlaps.

This example implements the following memory configuration:

- 2 GB total RAM size
- 0—512 MB dedicated secure area
- 513—576 MB shared area
- 577—2048 MB dedicated non-secure area

Figure 11-7: Example Memory Configuration



In this example, each port is configured by default to disallow all accesses. The following table shows the two rules programmed into the memory protection table.

Table 11-7: Rules in Memory Protection Table for Example Configuration

Rule #	Port Mask	AxID Low	AxID High	Address Low	Address High	Prot	Fail/Allow
1	0x3FF (1023)	0x000	0xFFF (4095)	0	576	1 (non-secure)	allow
2	0x3FF (1023)	0x000	0xFFF (4095)	512	2047	0 (secure)	allow

The port mask value, AxID Low, and AxID High, apply to all ports and all transfers within those ports. Each access request is evaluated against the memory protection table, and will fail unless there is a rule match allowing a transaction to complete successfully.

The following table shows the result for a sample set of transactions.

Table 11-8: Result for a Sample Set of Transactions

Operation	Source	Address Accesses	Security Access Type	Result	Comments
Read	CPU	4096	secure	Allow	Matches rule 1.
Write	CPU	536, 870, 912	secure	Allow	Matches rule 1.

Operation	Source	Address Accesses	Security Access Type	Result	Comments
Write	L3 attached masters	605, 028, 350	secure	Fail	Does not match rule 1 (out of range of the address field), does not match rule 2 (protection bit incorrect).
Read	L3 attached masters	4096	non-secure	Fail	Does not match rule 1 (prot value wrong), does not match rule 2 (not in address range).
Write	CPU	536, 870, 912	non-secure	Allow	Matches rule 2.
Write	L3 attached masters	605, 028, 350	non-secure	Allow	Matches rule 2.

If you did not want any overlap between the memory blocks, you could specify the address ranges in the two rules of the Memory Protection Table to be mutually exclusive. Depending on your desired TrustZone configuration, you can add rules to the memory protection table to create multiple blocks of protected or unprotected space.

SDRAM Power Management

The SDRAM controller subsystem supports the following power saving features in the SDRAM:

- Partial array self-refresh (PASR)
- Power down
- Deep power down for LPDDR2

To enable self-refresh for the memories of one or both chip selects, program the `selfshreq` bit and the `sefrfshmask` bit in the `lowpwreq` register.

Power-saving mode initiates either due to a user command or from inactivity. The number of idle clock cycles after which a memory can be put into power-down mode is programmed through the `autopdycycles` field of the `lowpwrtiming` register.

Power-down mode forces the SDRAM burst-scheduling bank-management logic to close all banks and issue the power down command. The SDRAM automatically reactivates when an active SDRAM command is received.

To enable deep power down request for the LPDDR2 memories of one or both chip selects, program the `deeppwrdnreq` bit and the `deepwrdnmask` field of the `lowpwreq` register.

Other power-down modes are performed only under user control.

DDR PHY

The DDR PHY connects the memory controller and external memory devices in the speed critical command path.

The DDR PHY implements the following functions:

- Calibration—the DDR PHY supports the JEDEC-specified steps to synchronize the memory timing between the controller and the SDRAM chips. The calibration algorithm is implemented in software.
- Memory device initialization—the DDR PHY performs the mode register write operations to initialize the devices. The DDR PHY handles re-initialization after a deep power down.
- Single-data-rate to double-data-rate conversion.

Clocks

All clocks are assumed to be asynchronous with respect to the `ddr_dqs_clk` memory clock. All transactions are synchronized to memory clock domain.

Table 11-9: SDRAM Controller Subsystem Clock Domains

Clock Name	Description
`ddr_dq_clk`	Clock for PHY
`ddr_dqs_clk`	Clock for MPFE, single-port controller, CSR access, and PHY
`ddr_2x_dqs_clk`	Clock for PHY that provides up to 2 times `ddr_dq_clk` frequency
`l4_sp_clk`	Clock for CSR interface
`mpu_l2_ram_clk`	Clock for MPU interface
`l3_main_clk`	Clock for L3 interface
`f2h_sdram_clk[5:0]`	Six separate clocks used for the FPGA-to-HPS SDRAM ports to the FPGA fabric

In terms of clock relationships, the FPGA fabric connects the appropriate clocks to write data, read data, and command ports for the constructed ports.

Related Information

Clock Manager on page 2-1

Resets

The SDRAM controller subsystem supports a full reset (cold reset) and a warm reset. The SDRAM controller can be configured to preserve memory contents during a warm reset.

To preserve memory contents, the reset manager can request that the single-port controller place the SDRAM in self-refresh mode prior to issuing the warm reset. If self-refresh mode is enabled before the warm reset to preserve memory contents, the PHY and the memory timing logic is not reset, but the rest of the controller is reset.

Reset Manager on page 3-1

Port Mappings

The memory interface controller has a set of command, read data, and write data ports that support AXI3, AXI4 and Avalon-MM. Tables are provided to identify port assignments and functions.

Table 11-10: Command Port Assignments

Command Port	Allowed Functions
0, 2, 4	FPGA fabric AXI read command ports FPGA fabric Avalon-MM read or write command ports
1, 3, 5	FPGA fabric AXI read command ports FPGA fabric Avalon-MM read or write command ports
6	L3 AXI read command port
7	MPU AXI read command port
8	L3 AXI write command port
9	MPU AXI write command port

Table 11-11: Read Port Assignments

Read Port	Allowed Functions
0, 1, 2, 3	64-bit read data from the FPGA fabric. When 128-bit data read ports are created, then read data ports 0 and1 get paired as well as 2 and 3.
4	32-bit L3 read data port
5	64-bit MPU read data port

Table 11-12: Write Port Assignments

Write Port	Allowed Functions
0, 1, 2, 3	64-bit write data from the FPGA fabric. When 128-bit data write ports are created, then write data ports 0 and 1 get paired as well as 2 and 3.
4	32-bit L3 write data port
5	64-bit MPU write data port

Initialization

The SDRAM controller subsystem has control and status registers (CSRs) which control the operation of the controller including DRAM type, DRAM timing parameters and relative port priorities. It also has a small set of bits which depend on the FPGA fabric to configure ports between the memory controller and the FPGA fabric; these bits are set for you when you configure your implementation using the HPS GUI in Qsys.

The CSRs are configured using a dedicated slave interface, which provides access to the registers. This region controls all SDRAM operation, MPFE scheduler configuration, and PHY calibration.

The FPGA fabric interface configuration is programmed into the FPGA fabric and the values of these register bits can be read by software. The ports can be configured without software developers needing to know how the FPGA-to-HPS SDRAM interface has been configured.

FPGA-to-SDRAM Protocol Details

The following topics summarize signals for the Avalon-MM Bidirectional port, Avalon-MM Write Port, Avalon-MM Read Port, and AXI port.

Note: If your device has multiple FPGA hardware images, then the same FPGA-to-SDRAM port configuration should be used across all designs.

Avalon-MM Bidirectional Port

The Avalon-MM bidirectional ports are standard Avalon-MM ports used to dispatch read and write operations.

Each configured Avalon-MM bidirectional port consists of the signals listed in the following table.

Table 11-13: Avalon-MM Bidirectional Port Signals

Name	Bit Width	Input/Output Direction	Function
`clk`	1	In	Clock for the Avalon-MM interface
`read`	1	In	Indicates read transaction [21]

[21] The Avalon-MM protocol does not allow read and write transactions to be posted concurrently.

Name	Bit Width	Input/Output Direction	Function
`write`	1	In	Indicates write transaction [21]
`address`	32	In	Address of the transaction
`readdata`	32, 64, 128, or 256	Out	Read data return
`readdatavalid`	1	Out	Indicates the `readdata` signal contains valid data in response to a previous read request.
`writedata`	32, 64, 128, or 256	In	Write data for a transaction
`byteenable`	4, 8, 16, 32	In	Byte enables for each write byte lane
`waitrequest`	1	Out	Indicates need for additional cycles to complete a transaction
`burstcount`	11	In	Transaction burst length. The value of the maximum `burstcount` parameter must be a power of 2.

The read and write interfaces are configured to the same size. The byte-enable size scales with the data bus size.

Information about the Avalon-MM protocol

Avalon-MM Write-Only Port

The Avalon-MM write-only ports are standard Avalon-MM ports used to dispatch write operations. Each configured Avalon-MM write port consists of the signals listed in the following table.

Table 11-14: Avalon-MM Write-Only Port Signals

Name	Bits	Direction	Function
`reset`	1	In	Reset
`clk`	1	In	Clock
`write`	1	In	Indicates write transaction

Name	Bits	Direction	Function
address	32	In	Address of the transaction
writedata	32, 64, 128, or 256	In	Write data for a transaction
byteenable	4, 8, 16, 32	In	Byte enables for each write byte
waitrequest	1	Out	Indicates need for additional cycles to complete a transaction
burstcount	11	In	Transaction burst length

Related Information

Avalon Interface Specifications

Information about the Avalon-MM protocol

Avalon-MM Read Port

The Avalon-MM read ports are standard Avalon-MM ports used only to dispatch read operations. Each configured Avalon-MM read port consists of the signals listed in the following table.

Table 11-15: Avalon-MM Read Port Signals

Name	Bits	Direction	Function
reset	1	In	Reset
clk	1	In	Clock
read	1	In	Indicates read transaction
address	32	In	Address of the transaction
readdata	32, 64, 128, or 256	Out	Read data return
readdatavalid	1	Out	Flags valid cycles for read data return
waitrequest	1	Out	Indicates the need for additional cycles to complete a transaction. Needed for read operations when delay is needed to accept the read command.
burstcount	11	In	Transaction burst length

Related Information

Avalon Interface Specifications

Information about the Avalon-MM protocol

AXI Port

The AXI port uses an AXI-3 interface. Each configured AXI port consists of the signals listed in the following table. Each AXI interface signal is independent of the other interfaces for all signals, including clock and reset.

Table 11-16: AXI Port Signals

Name	Bits	Direction	Function
`ARESETn`	1	In	Reset
`ACLK`	1	In	Clock
Name	**Bits**	**Direction**	**Function**
Write Address Channel Signals			
`AWID`	4	In	Write identification tag
`AWADDR`	32	In	Write address
`AWLEN`	4	In	Write burst length
`AWSIZE`	3	In	Width of the transfer size
`AWBURST`	2	In	Burst type
`AWLOCK`	2	In	Lock type signal which indicates if the access is exclusive; valid values are 0x0 (normal access) and 0x1 (exclusive access)
`AWCACHE`	4	In	Cache policy type
`AWPROT`	3	In	Protection-type signal used to indicate whether a transaction is secure or non-secure

Name	Bits	Direction	Function
AWREADY	1	Out	Indicates ready for a write command
AWVALID	1	In	Indicates valid write command.
Name	Bits	Direction	Function
Write Data Channel Signals			
WID	4	In	Write data transfer ID
WDATA	32, 64, 128 or 256	In	Write data
WSTRB	4, 8, 16, 32	In	Byte-based write data strobe. Each bit width corresponds to 8 bit wide transfer for 32-bit wide to 256-bit wide transfer.
WLAST	1	In	Last transfer in a burst
WVALID	1	In	Indicates write data and strobes are valid
WREADY	1	Out	Indicates ready for write data and strobes
Name	Bits	Direction	Function
Write Response Channel Signals			
BID	4	Out	Write response transfer ID
BRESP	2	Out	Write response status
BVALID	1	Out	Write response valid signal
BREADY	1	In	Write response ready signal
Name	Bits	Direction	Function
Read Address Channel Signals			

Name	Bits	Direction	Function
ARID	4	In	Read identification tag
ARADDR	32	In	Read address
ARLEN	4	In	Read burst length
ARSIZE	3	In	Width of the transfer size
ARBURST	2	In	Burst type
ARLOCK	2	In	Lock type signal which indicates if the access is exclusive; valid values are 0x0 (normal access) and 0x1 (exclusive access)
ARCACHE	4	In	Lock type signal which indicates if the access is exclusive; valid values are 0x0 (normal access) and 0x1 (exclusive access)
ARPROT	3	In	Protection-type signal used to indicate whether a transaction is secure or non-secure
ARREADY	1	Out	Indicates ready for a read command
ARVALID	1	In	Indicates valid read command
Name	Bits	Direction	Function
Read Data Channel Signals			
RID	4	Out	Read data transfer ID
RDATA	32, 64, 128 or 256	Out	Read data
RRESP	2	Out	Read response status

Name	Bits	Direction	Function
RLAST	1	Out	Last transfer in a burs
RVALID	1	Out	Indicates read data is valid
RREADY	1	In	Read data channel ready signal

SDRAM Controller Subsystem Programming Model

SDRAM controller configuration occurs through software programming of the configuration registers using the CSR interface.

HPS Memory Interface Architecture

The configuration and initialization of the memory interface by the ARM processor is a significant difference compared to the FPGA memory interfaces, and results in several key differences in the way the HPS memory interface is defined and configured.

Boot-up configuration of the HPS memory interface is handled by the initial software boot code, not by the FPGA programmer, as is the case for the FPGA memory interfaces. The Quartus II software is involved in defining the configuration of I/O ports which is used by the boot-up code, as well as timing analysis of the memory interface. Therefore, the memory interface must be configured with the correct PHY-level timing information. Although configuration of the memory interface in Qsys is still necessary, it is limited to PHY- and board-level settings.

HPS Memory Interface Configuration

To configure the external memory interface components of the HPS, open the HPS interface by selecting the Arria V/Cyclone V Hard Processor System component in Qsys. Within the HPS interface, select the EMIF tab to open the EMIF parameter editor.

The EMIF parameter editor contains four additional tabs: PHY Settings, Memory Parameters, Memory Timing, and Board Settings. The parameters available on these tabs are similar to those available in the parameter editors for non-SoC device families.

There are significant differences between the EMIF parameter editor for the Hard Processor System and the parameter editors for non-SoC devices, as follows:

- Because the HPS memory controller is not configurable through the Quartus II software, the Controller and Diagnostic tabs, which exist for non-SoC devices, are not present in the EMIF parameter editor for the hard processor system.
- Unlike the protocol-specific parameter editors for non-SoC devices, the EMIF parameter editor for the Hard Processor System supports multiple protocols, therefore there is an SDRAM Protocol parameter, where you can specify your external memory interface protocol. By default, the EMIF parameter editor assumes the DDR3 protocol, and other parameters are automatically populated with DDR3-appropriate values. If you select a protocol other than DDR3, change other associated parameter values appropriately.
- Unlike the memory interface clocks in the FPGA, the memory interface clocks for the HPS are initialized by the boot-up code using values provided by the configuration process. You may accept the values provided by UniPHY, or you may use your own PLL settings. If you choose to specify your own PLL settings, you must indicate that the clock frequency that UniPHY should use is the requested clock frequency, and not the achieved clock frequency calculated by UniPHY.

Note: The HPS does not support EMIF synthesis generation, compilation, or timing analysis. The HPS hard memory controller cannot be bonded with another hard memory controller on the FPGA portion of the device.

HPS Memory Interface Simulation

Qsys provides a complete simulation model of the HPS memory interface controller and PHY, providing cycle-level accuracy, comparable to the simulation models for the FPGA memory interface.

The simulation model supports only the skip-cal simulation mode; quick-cal and full-cal are not supported. An example design is not provided, however you can create a test design by adding the traffic generator component to your design using Qsys. Also, the HPS simulation model does not use external memory pins to connect to the DDR memory model; instead, the memory model is incorporated directly into the HPS SDRAM interface simulation modules. The memory instance incorporated into the HPS model is in the simulation model hierarchy at: **hps_0/fpga_interfaces/f2sdram/hps_sdram_inst/mem/**

Simulation of the FPGA-to-SDRAM interfaces requires that you first bring the interfaces out of reset, otherwise transactions cannot occur. Connect the H2F reset to the F2S port resets and add a stage to your testbench to assert and deassert the H2F reset in the HPS. Appropriate Verilog code is shown below:

```
initial
begin
   // Assert reset
   <base name>.hps.fpga_interfaces.h2f_reset_inst.reset_assert();
   // Delay
   #1
   // Deassert reset
   <base name>.hps.fpga_interfaces.h2f_reset_inst.reset_deassert();
end
```

Generating a Preloader Image for HPS with EMIF

To generate a Preloader image for an HPS-based external memory interface, you must complete the following tasks:

- Create a Qsys project.
- Create a top-level file and add constraints.
- Create a Preloader BSP file.
- Create a Preloader image.

Creating a Qsys Project in Preparation for Generating a Preloader Image

This topic describes creating a Qsys project in preparation for generating a Preloader image.

1. On the **Tools** menu in the Quartus II software, click **Qsys**.
2. Under **Component library**, expand **Embedded Processor System**, select **Hard Processor System** and click **Add**.
3. Specify parameters for the **FPGA Interfaces**, **Peripheral Pin Multiplexing**, and **HPS Clocks**, based on your design requirements.
4. On the **SDRAM** tab, select the SDRAM protocol for your interface.
5. Populate the necessary parameter fields on the **PHY Settings**, **Memory Parameters**, **Memory Timing**, and **Board Settings** tabs.
6. Add other Qsys components in your Qsys design and make the appropriate bus connections.
7. Save the Qsys project.
8. Click **Generate** on the **Generation** tab, to generate the Qsys design.

Creating a Top-Level File and Adding Constraints

This topic describes adding your Qsys system to your top-level design and adding constraints to your design.

1. Add your Qsys system to your top-level design.
2. Add the Quartus II IP files (**.qip**) generated in step 2, to your Quartus II project.
3. Perform analysis and synthesis on your design.
4. Constrain your EMIF design by running the **<*variation_name*>_p0_pin_assignments.tcl** pin constraints script.
5. Add other necessary constraints—such as timing constraints, location assignments, and pin I/O standard assignments—for your design.
6. Compile your design to generate an SRAM object file (**.sof**) and the hardware handoff files necessary for creating a preloader image.

   Note: You must regenerate the hardware handoff files whenever the HPS configuration changes; for example, due to changes in Peripheral Pin Multiplexing or I/O standard for HPS pins.

Altera SoC Embedded Design Suite User's Guide

For more information on how to create a preloader BSP file and image.

Debugging HPS SDRAM in the Preloader

To assist in debugging your design, tools are available at the preloader stage.

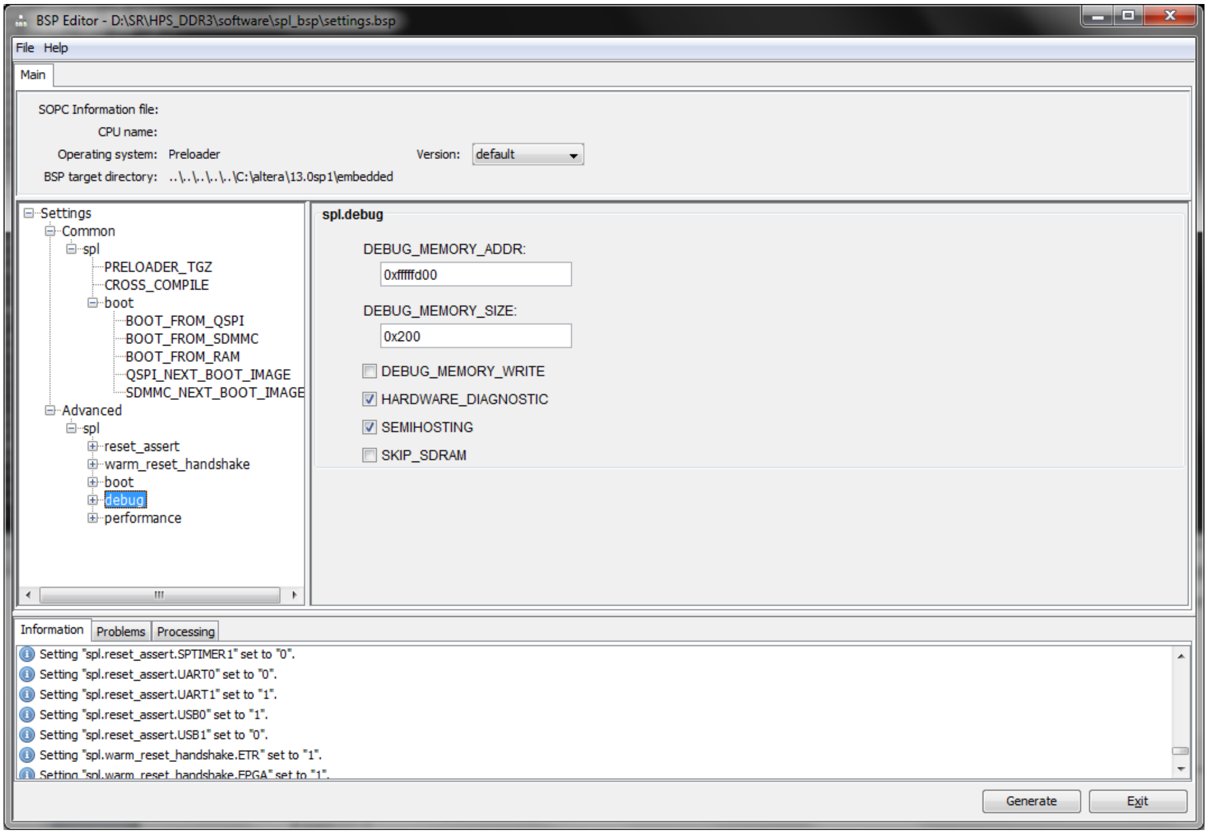
- UART or semihosting printout
- Simple memory test
- Debug report
- Predefined data patterns

The following topics provide procedures for implementing each of the above tools.

Enabling UART or Semihosting Printout

UART printout is enabled by default. If UART is not available on your system, you can use semihosting together with the debugger tool. To enable semihosting in the Preloader, follow these steps:

1. When you create the **.bsp** file in the BSP Editor, select **SEMIHOSTING** in the **spl.debug** window.



SOPC Information file:
CPU name:
Operating system: Preloader
Version: default
BSP target directory: ..\..\..\..\..\C:\altera\13.0sp1\embedded

spl.debug

```

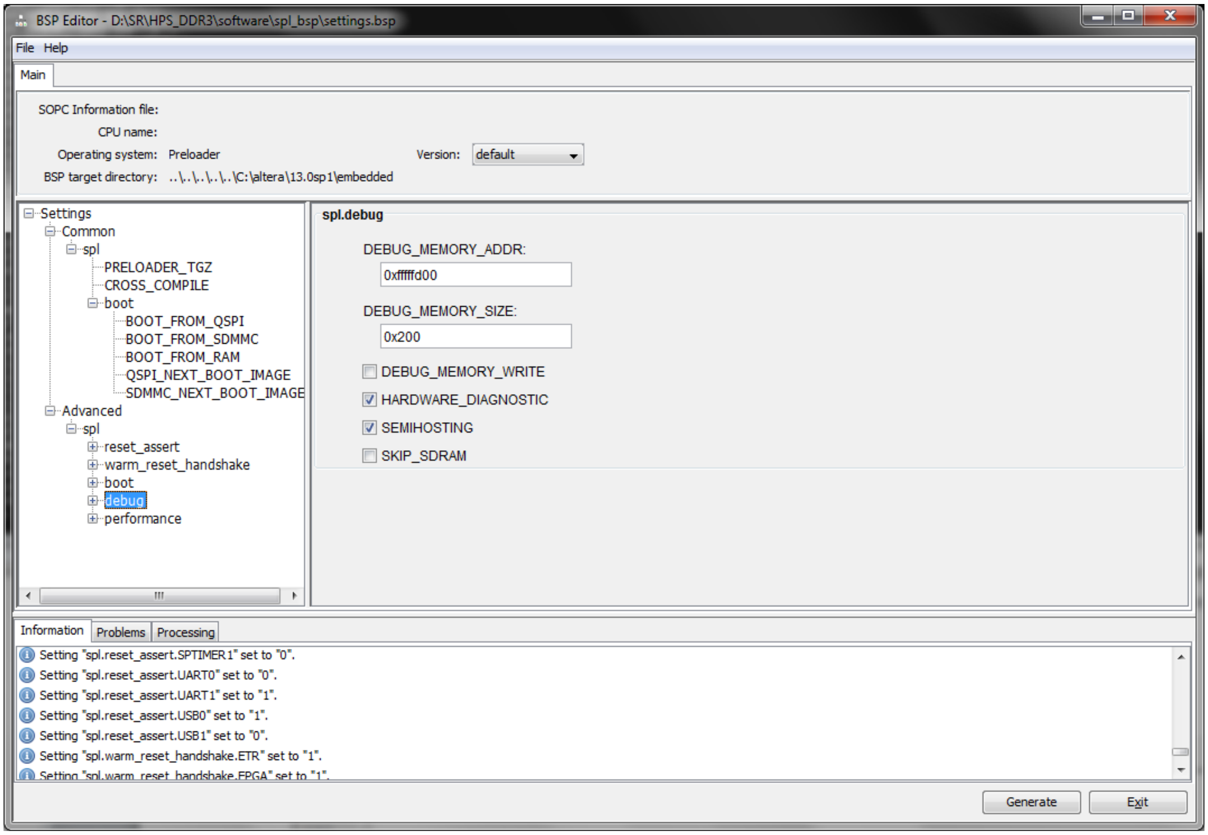
Command: set semihosting enabled true

Enabling Simple Memory Test

After the SDRAM is successfully calibrated, a simple memory test may be performed using the debugger.

1. When you create the **.bsp** file in the BSP Editor, select **HARDWARE_DIAGNOSTIC** in the **spl.debug** window..



SOPC Information file:
CPU name:
Operating system: Preloader Version: default
BSP target directory: ..\..\..\..\..\C:\altera\13.0sp1\embedded

spl.debug

DEBUG_MEMORY_ADDR: 0xffffd00

DEBUG_MEMORY_SIZE: 0x200

□ DEBUG_MEMORY_WRITE

☑ HARDWARE_DIAGNOSTIC

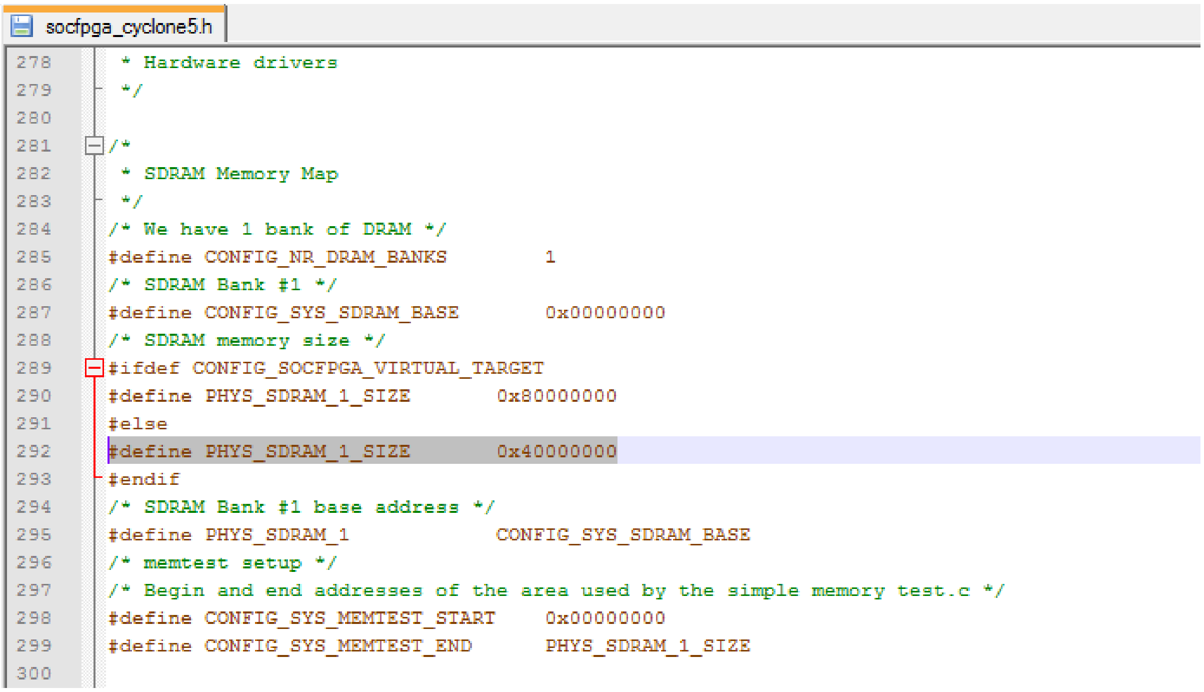
☑ SEMIHOSTING

□ SKIP_SDRAM

```
Setting "spl.reset_assert.SPTIMER1" set to "0".
Setting "spl.reset_assert.UART0" set to "0".
Setting "spl.reset_assert.UART1" set to "1".
Setting "spl.reset_assert.USB0" set to "1".
Setting "spl.reset_assert.USB1" set to "0".
Setting "spl.warm_reset_handshake.ETR" set to "1".
Setting "spl.warm_reset_handshake.FPGA" set to "1".
```

2. The simple memory test assumes SDRAM with a memory size of 1 GB. If your board contains a different SDRAM memory size, open the file **<*design folder*>\spl_bsp\uboot-socfpga\include\configs\**

socfpga_cyclone5.h in a text editor, and change the `PHYS_SDRAM_1_SIZE` parameter at line 292 to specify your actual memory size in bytes.



```
278  * Hardware drivers
279  */
280
281 /*
282  * SDRAM Memory Map
283  */
284 /* We have 1 bank of DRAM */
285 #define CONFIG_NR_DRAM_BANKS        1
286 /* SDRAM Bank #1 */
287 #define CONFIG_SYS_SDRAM_BASE       0x00000000
288 /* SDRAM memory size */
289 #ifdef CONFIG_SOCFPGA_VIRTUAL_TARGET
290 #define PHYS_SDRAM_1_SIZE       0x80000000
291 #else
292 #define PHYS_SDRAM_1_SIZE       0x40000000
293 #endif
294 /* SDRAM Bank #1 base address */
295 #define PHYS_SDRAM_1            CONFIG_SYS_SDRAM_BASE
296 /* memtest setup */
297 /* Begin and end addresses of the area used by the simple memory test.c */
298 #define CONFIG_SYS_MEMTEST_START    0x00000000
299 #define CONFIG_SYS_MEMTEST_END      PHYS_SDRAM_1_SIZE
300
```

Enabling the Debug Report

You can enable the SDRAM calibration sequencer to produce a debug report on the UART printout or semihosting output. To enable the debug report, follow these steps:

1. After you have enabled the UART or semihosting, open the file **<*project directory*>\hps_isw_handoff\sequencer_defines.h**in a text editor.
2. Locate the line `#define RUNTIME_CAL_REPORT 0` and change it to `#define RUNTIME_CAL_REPORT 1`.

```

Analysis of Debug Report

The following analysis will help you interpret the debug report.

- The Read Deskew and Write Deskew results shown in the debug report are before calibration. (Before calibration results are actually from the window seen *during* calibration, and are most useful for debugging.)
- For each DQ group, the Write Deskew, Read Deskew, DM Deskew, and Read after Write results map to the before-calibration margins reported in the EMIF Debug Toolkit.

  Note: The Write Deskew, Read Deskew, DM Deskew, and Read after Write results are reported in delay steps (nominally 25ps, in Arria V and Cyclone V devices), not in picoseconds.
- DQS Enable calibration is reported as a VFIFO setting (in one clock period steps), a phase tap (in one-eighth clock period steps), and a delay chain step (in 25ps steps).

```
SEQ.C: DQS Enable ; Group 0 ; Rank 0 ; Start  VFIFO  5 ; Phase 6 ; Delay  4
SEQ.C: DQS Enable ; Group 0 ; Rank 0 ; End    VFIFO  6 ; Phase 5 ; Delay  9
SEQ.C: DQS Enable ; Group 0 ; Rank 0 ; Center VFIFO  6 ; Phase 2 ; Delay  1
```

  Analysis of DQS Enable results: A VFIFO tap is 1 clock period, a phase is 1/8 clock period (45 degrees) and delay is nominally 25ps per tap. The DQSen window is the difference between the start and end—for the above example, assuming a frequency of 400 MHz (2500ps), that calculates as follows: `start is 5*2500 + 6*2500/8 +4*25 = 14475ps`. By the same calculation, the end is 16788ps. Consequently, the DQSen window is 2313ps.
- The size of a read window or write window is equal to `(left edge + right edge) * delay chain step size`. Both the left edge and the right edge can be negative or positive.:

```
SEQ.C: Read Deskew  ; DQ  0 ; Rank 0 ; Left edge  18 ; Right edge  27 ; DQ
delay  0 ; DQS delay  8
SEQ.C: Write Deskew ; DQ  0 ; Rank 0 ; Left edge  30 ; Right edge  17 ; DQ
delay  6 ; DQS delay  4
```

  Analysis of DQ and DQS delay results: The DQ and DQS output delay (write) is the D5 delay chain. The DQ input delay (read) is the D1 delay chain, the DQS input delay (read) is the D4 delay chain.
- Consider the following example of latency results:

```
SEQ.C: LFIFO Calibration ; Latency 10
```

  Analysis of latency results: This is the calibrated PHY read latency. The EMIF Debug Toolkit does not report this figure. This latency is reported in clock cycles.
- Consider the following example of FOM results:

```
SEQ.C: FOM IN  = 83
SEQ.C: FOM OUT = 91
```

  Analysis of FOM results: The FOM IN value is a measure of the health of the read interface; it is calculated as the sum over all groups of the minimum margin on DQ plus the margin on DQS, divided by 2. The FOM OUT is a measure of the health of the write interface; it is calculated as the sum over all groups of the minimum margin on DQ plus the margin on DQS, divided by 2. You may refer to these values as indicators of improvement when you are experimenting with various termination schemes, assuming there are no individual misbehaving DQ pins.
- The debug report does not provide delay chain step size values. The delay chain step size varies with device speed grade. Refer to your device data sheet for exact incremental delay values for delay chains.

For more information about calibration, refer to the *Calibration Stages* section in the *Functional Description-UniPHY* chapter of the *External Memory Interface Handbook*.

Writing a Predefined Data Pattern to SDRAM in the Preloader

You can include your own code to write a predefined data pattern to the SDRAM in the preloader for debugging purposes.

1. Include your code in the file: **<*project_folder*>\software\spl_bsp\uboot-socfpga\arch\arm\cpu\armv7\socfpga\spl.c** .
   Adding the following code to the **spl.c** file causes the controller to write walking 1s and walking 0s, repeated five times, to the SDRAM.

```
/*added for demo, place after the last #define statement in spl.c */
#define ROTATE_RIGHT(X) ( (X>>1) | (X&1?0X80000000:0) )
/*added for demo, place after the calibration code */
 test_data_walk0((long *)0x100000,PHYS_SDRAM_1_SIZE);
int test_data_walk0(long *base, long maxsize)
{
    volatile long *addr;
    long           cnt;
    ulong           data_temp[3];
        ulong           expected_data[3];
    ulong           read_data;
        int            i = 0;  //counter to loop different data pattern
        int           num_address;

       num_address=50;

       data_temp[0]=0XFFFFFFFE; //initial data for walking 0 pattern
       data_temp[1]=0X00000001; //initial data for walking 1 pattern
       data_temp[2]=0XAAAAAAAA; //initial data for A->5 switching

       expected_data[0]=0XFFFFFFFE; //initial data for walking 0 pattern
       expected_data[1]=0X00000001; //initial data for walking 1 pattern
       expected_data[2]=0XAAAAAAAA; //initial data for A->5 switching

       for (i=0;i<3;i++) {

    printf("\nSTARTED %08X DATA PATTERN !!!!\n",data_temp[i]);
    /*write*/
    for (cnt = (0+i*num_address); cnt < ((i+1)*num_address) ;  cnt++ ) {
        addr = base + cnt;    /* pointer arith! */
        sync ();
            *addr = data_temp[i];
        data_temp[i]=ROTATE_RIGHT(data_temp[i]);

        }

    /*read*/
    for (cnt = (0+i*num_address); cnt < ((i+1)*num_address) ; cnt = cnt++ ) {
        addr = base + cnt;    /* pointer arith! */
        sync ();
        read_data=*addr;
              printf("Address:%X  Expected: %08X    Read:%08X \n",addr,
expected_data[i],read_data);
               if (expected_data[i] !=read_data) {
                puts("!!!!!!FAILED!!!!!!\n\n");
        hang();
            }
                expected_data[i]=ROTATE_RIGHT(expected_data[i]);
}
}
}
====//End Of Code//=====
```

SDRAM Controller Module Register Descriptions

Address map for the SDRAM controller and multi-port front-end. All registers in this group reset to zero.

Offset: 0x5000

ctrlcfg on page 11-42
The Controller Configuration Register determines the behavior of the controller.

dramtiming1 on page 11-44
This register implements JEDEC standardized timing parameters. It should be programmed in clock cycles, for the value specified by the memory vendor.

dramtiming2 on page 11-45
This register implements JEDEC standardized timing parameters. It should be programmed in clock cycles, for the value specified by the memory vendor.

dramtiming3 on page 11-46
This register implements JEDEC standardized timing parameters. It should be programmed in clock cycles, for the value specified by the memory vendor.

dramtiming4 on page 11-46
This register implements JEDEC standardized timing parameters. It should be programmed in clock cycles, for the value specified by the memory vendor.

lowpwrtiming on page 11-47
This register controls the behavior of the low power logic in the controller.

dramodt on page 11-48
This register controls which ODT pin asserts with chip select 0 (CS0) assertion and which ODT pin asserts with chip select 1 (CS1) assertion.

dramaddrw on page 11-49
This register configures the width of the various address fields of the DRAM. The values specified in this register must match the memory devices being used.

dramifwidth on page 11-49
This register controls the interface width of the SDRAM controller.

dramsts on page 11-50
This register provides the status of the calibration and ECC logic.

dramintr on page 11-51
This register can enable, disable and clear the SDRAM error interrupts.

sbecount on page 11-51
This register tracks the single-bit error count.

dbecount on page 11-52
This register tracks the double-bit error count.

erraddr on page 11-52
This register holds the address of the most recent ECC error.

dropcount on page 11-53
This register holds the address of the most recent ECC error.

dropaddr on page 11-53
This register holds the last dropped address.

lowpwreq on page 11-54
This register instructs the controller to put the DRAM into a power down state. Note that some commands are only valid for certain memory types.

lowpwrack on page 11-55
This register gives the status of the power down commands requested by the Low Power Control register.

staticcfg on page 11-55
This register controls configuration values which cannot be updated during active transfers. First configure the `membl` and `eccn` fields and then re-write these fields while setting the `applycfg` bit. The `applycfg` bit is write only.

ctrlwidth on page 11-56
This register controls the width of the physical DRAM interface.

portcfg on page 11-57
Each bit of the `autopchen` field maps to one of the control ports. If a port executes mostly sequential memory accesses, the corresponding `autopchen` bit should be 0. If the port has highly random accesses, then its `autopchen` bit should be set to 1.

fpgaportrst on page 11-58
This register implements functionality to allow the CPU to control when the MPFE will enable the ports to the FPGA fabric.

protportdefault on page 11-59
This register controls the default protection assignment for a port. Ports which have explicit rules which define regions which are illegal to access should set the bits to pass by default. Ports which have explicit rules which define legal areas should set the bit to force all transactions to fail. Leaving this register to all zeros should be used for systems which do not desire any protection from the memory controller.

protruleaddr on page 11-59
This register is used to control the memory protection for port 0 transactions. Address ranges can either be used to allow access to memory regions or disallow access to memory regions. If TrustZone is being used, access can be enabled for protected transactions or disabled for unprotected transactions. The default state of this register is to allow all access. Address values used for protection are only physical addresses.

protruleid on page 11-60
This register configures the AxID for a given protection rule.

protruledata on page 11-61
This register configures the protection memory characteristics of each protection rule.

protrulerdwr on page 11-62
This register is used to perform read and write operations to the internal protection table.

mppriority on page 11-63
This register is used to configure the DRAM burst operation scheduling.

remappriority on page 11-63
This register applies another level of port priority after a transaction is placed in the single port queue.

Port Sum of Weight Register Register Descriptions on page 11-64
This register is used to configure the DRAM burst operation scheduling.

ctrlcfg

The Controller Configuration Register determines the behavior of the controller.

Module Instance	Base Address	Register Address
sdr	0xFFC20000	0xFFC25000

Offset: 0x5000

Access: RW

reorderen RW 0x0	gendbe RW 0x0	gensbe RW 0x0	cfg_enable_ecc_code_overwrites RW 0x0	ecccorren RW 0x0	eccen RW 0x0	addrorder RW 0x0		membl RW 0x0					memtype RW 0x0		

ctrlcfg Fields

Bit	Name	Description	Access	Reset
25	bursttermen	Set to a one to enable the controller to issue burst terminate commands. This must only be set when the DRAM memory type is LPDDR2.	RW	0x0
24	burstintren	Set to a one to enable the controller to issue burst interrupt commands. This must only be set when the DRAM memory type is LPDDR2.	RW	0x0
23	nodmpins	Set to a one to enable DRAM operation if no DM pins are connected.	RW	0x0
22	dqstrken	Enables DQS tracking in the PHY.	RW	0x0
21:16	starvelimit	Specifies the number of DRAM burst transactions an individual transaction will allow to reorder ahead of it before its priority is raised in the memory controller.	RW	0x0
15	reorderen	This bit controls whether the controller can re-order operations to optimize SDRAM bandwidth. It should generally be set to a one.	RW	0x0
14	gendbe	Enable the deliberate insertion of double bit errors in data written to memory. This should only be used for testing purposes.	RW	0x0
13	gensbe	Enable the deliberate insertion of single bit errors in data written to memory. This should only be used for testing purposes.	RW	0x0
12	cfg_enable_ecc_code_ overwrites	Set to a one to enable ECC overwrites. ECC overwrites occur when a correctable ECC error is seen and cause a new read/modify/write to be scheduled for that location to clear the ECC error.	RW	0x0
11	ecccorren	Enable auto correction of the read data returned when single bit error is detected.	RW	0x0
10	eccen	Enable the generation and checking of ECC. This bit must only be set if the memory connected to the SDRAM interface is 24 or 40 bits wide. If you set this, you must clear the useeccasdata field in the staticcfg register.	RW	0x0

Bit	Name	Description	Access	Reset
9:8	addrorder	This bit field selects the order for address interleaving. Programming this field with different values gives different mappings between the AXI or Avalon-MM address and the SDRAM address. Program this field with the following binary values to select the ordering. **Value** **Description** 0x0 chip, row, bank, column 0x1 chip, bank, row, column 0x2 row, chip, bank, column 0x3 reserved	RW	0x0
7:3	membl	This bit field configures burst length as a static decimal RW 0x0 value. These values are valid for JEDEC allowed DRAMs configured by programming the `memtype` field. The membl field is programmed as follows: For DDR3, program `membl` to 0x8; for DDR2, `membl` can be 0x4 or 0x8, depending on the DRAM chip; for LPDDR2, `membl` can be programmed with 0x4, 0x8 or 0x10; for LPDDR, `membl` can be 0x2, 0x4 or 0x8.	RW	0x0
2:0	memtype	This bit field selects the memory type. This field can be programmed with the following binary values: **Value** **Description** 0x0 Memory type is DDR2 SDRAM 0x1 Memory type is DDR3 SDRAM 0x2 Memory type is LPDDR1 SDRAM 0x3 Memory type is LPDR2 SDRAM 0x4-0x7 These bits are reserved.	RW	0x0

dramtiming1

This register implements JEDEC standardized timing parameters. It should be programmed in clock cycles, for the value specified by the memory vendor.

Module Instance	Base Address	Register Address

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved										selfrfshmask RW 0x0		selfrshreq RW 0x0	deeppwrdnmask RW 0x0		deeppwrdnreq RW 0x0

lowpwreq Fields

Bit	Name	Description	Access	Reset
5:4	selfrfshmask	Write a one to each bit of this field to have a self refresh request apply to both chips.	RW	0x0
3	selfrshreq	Write a one to this bit to request the RAM be put into a self refresh state. This bit is treated as a static value so the RAM will remain in self-refresh as long as this register bit is set to a one. This power down mode can be selected for all DRAMs supported by the controller.	RW	0x0

Bit	Name	Description	Access	Reset
2:1	deeppwrdnmask	Write ones to this register to select which DRAM chip selects will be powered down. Typical usage is to set both of these bits when deeppwrdnreq is set but the controller does support putting a single chip into deep power down and keeping the other chip running.	RW	0x0
0	deeppwrdnreq	Write a one to this bit to request a deep power down. This bit should only be written with LPDDR2 DRAMs, DDR3 DRAMs do not support deep power down.	RW	0x0

lowpwrack

This register gives the status of the power down commands requested by the Low Power Control register.

Module Instance	Base Address	Register Address
sdr	0xFFC20000	0xFFC25058

Offset: 0x5058

Access: RW

Reserved												applycfg RW 0x0	useeccasdata RW 0x0	membl RW 0x0	

staticcfg Fields

Bit	Name	Description	Access	Reset
3	applycfg	Write with this bit set to apply all the settings loaded in SDR registers to the memory interface. This bit is write-only and always returns 0 if read.	RW	0x0
2	useeccasdata	This field allows the FPGA ports to directly access the extra data bits that are normally used to hold the ECC code. The interface width must be set to 24 or 40 in the dramifwidth register. If you set this, you must clear the eccen field in the ctrlcfg register.	RW	0x0
1:0	membl	This bit field configures the DRAM burst length. For DDR3, program membl to 0x8; for DDR2, membl can be 0x4 or 0x8, depending on the DRAM chip; for LPDDR2, membl can be programmed with 0x4, 0x8 or 0x10; for LPDDR, membl can be 0x2, 0x4 or 0x8. If this field is programmed, the membl field in the ctrlcfg register must also be programmed.	RW	0x0

ctrlwidth

This register controls the width of the physical DRAM interface.

Module Instance	Base Address	Register Address
sdr	0xFFC20000	0xFFC25060

Offset: 0x5060

Access: RW

Bit Fields

Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved		portrstn RW 0x0													

fpgaportrst Fields

Bit	Name	Description	Access	Reset
13:0	`portrstn`	This register should be written to with a 1 to enable the selected FPGA port to exit reset. Writing a bit to a zero will stretch the port reset until the register is written. Read data ports are connected to bits 3:0, with read data port 0 at bit 0 to read data port 3 at bit 3. Write data ports 0 to 3 are mapped to 4 to 7, with write data port 0 connected to bit 4 to write data port 3 at bit 7. Command ports are connected to bits 8 to 13, with command port 0 at bit 8 to command port 5 at bit 13. Expected usage would be to set all the bits at the same time but setting some bits to a zero and others to a one is supported.	`RW`	`0x0`

protportdefault

This register controls the default protection assignment for a port. Ports which have explicit rules which define regions which are illegal to access should set the bits to pass by default. Ports which have explicit rules which define legal areas should set the bit to force all transactions to fail. Leaving this register to all zeros should be used for systems which do not desire any protection from the memory controller.

Module Instance	Base Address	Register Address
sdr	0xFFC20000	0xFFC2508C

Offset: 0x508C

Access: RW

protrulerdwr Fields

Bit	Name	Description	Access	Reset
6	readrule	Write to this bit to have the memory_prot_data register loaded with the value from the internal protection table at offset. Table value will be loaded before a rdy is returned so read data from the register will be correct for any follow-on reads to the memory_prot_data register.	RW	0x0
5	writerule	Write to this bit to have the memory_prot_data register to the table at the offset specified by port_offset. Bit automatically clears after a single cycle and the write operation is complete.	RW	0x0

Bit	Name	Description	Access	Reset
4:0	`ruleoffset`	This field defines which of the 20 rules in the protection table you want to read or write.	`RW`	`0x0`

mppriority

This register is used to configure the DRAM burst operation scheduling.

Module Instance	Base Address	Register Address
`sdr`	`0xFFC20000`	`0xFFC250AC`

Offset: `0x50AC`

Access: `RW`

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved		userpriority RW 0x0													
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
userpriority RW 0x0															

mppriority Fields

Bit	Name	Description	Access	Reset
29:0	`userpriority`	User Priority: This field sets the absolute user priority of each port, which is represented as a 3-bit value. 0x0 is the lowest priority and 0x7 is the highest priority. Port 0 is configured by programming `userpriority[2:0]`, port 1 is configured by programming `userpriority[5:3]`, port 2 is configured by programming `userpriority[8:6]`, and so on.	`RW`	`0x0`

remappriority

This register applies another level of port priority after a transaction is placed in the single port queue.

Module Instance	Base Address	Register Address
`sdr`	`0xFFC20000`	`0xFFC250E0`

Offset: `0x50E0`

Access: `RW`

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved								priorityremap RW 0x0							

remappriority Fields

Bit	Name	Description	Access	Reset
7:0	`priorityremap`	Each bit of this field represents a priority level. If bit N in the `priorityremap` field is set, then any port transaction with absolute user priority of N jumps to the front of the single port queue and is serviced ahead of any tranactions in the queue. For example, if bit 5 is set in the `priorityremap` field of the `remappriority` register, then any port transaction with a `userpriority` value of 0x5 in the `mppriority` register is serviced ahead of any other transaction already in the single port queue.	RW	0x0

Port Sum of Weight Register Register Descriptions

Document Revision History

Date	Version	Changes
June 2014	2014.6.30	• Added *Port Mappings* section. • Added *SDRAM Controller Memory Options* section. • Enhanced *Example of Configuration for TrustZone* section. • Added SDRAM Controller address map and registers.
December 2013	2013.12.30	• Added *Generating a Preloader Image for HPS with EMIF* section. • Added *Debugging HPS SDRAM in the Preloader* section. • Enhanced *Simulation* section.
November 2012	1.1	Added address map and register definitions section.
January 2012	1.0	Initial release.

On-Chip Memory 12

2014.06.30

cv_54009 Subscribe Send Feedback

The hard processor system (HPS) contains two types of on-chip memory. The on-chip memory types are the following:

- On-Chip RAM—The on-chip RAM provides 64 KB of general-purpose RAM.
- Boot ROM—The boot ROM contains the code required to boot the HPS from cold or warm reset.

Both memories connect to the level 3 (L3) interconnect.

Related Information

- **On-Chip RAM** on page 12-1
- **Boot ROM** on page 12-3

On-Chip RAM

Features of the On-Chip RAM

The on-chip RAM offers the following features:

- 64-bit slave interface
- 64 KB size
- Single-ported RAM
- Read acceptance of two, write acceptance of two, and a total acceptance of four
- Error correction code (ECC) support
- High throughput - read or write every clock cycle.

Related Information

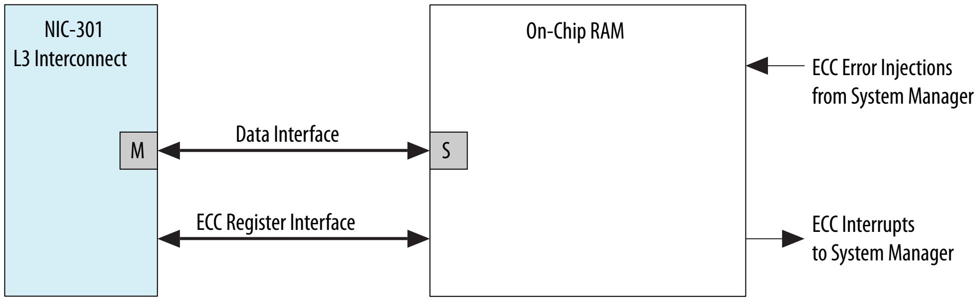
Clock Manager on page 2-1
For more information about the operating frequency and maximum throughput, refer to the *Clock Manager* chapter.

On-Chip RAM Block Diagram and System Integration

Transfers between memory and the NIC-301 L3 interconnect happen through a 64-bit interface, gated by the `l3_main_clk` interconnect clock. ECC logic detects single-bit, corrected and double-bit, uncorrected errors. The memory has a read acceptance of two, a write acceptance of two, and a total acceptance of two with round-robin arbitration.

The entire RAM is either secure or non-secure. Security is enforced by the NIC-301 L3 interconnect.

Figure 12-1: On-Chip RAM Block Diagram



Note: You must initialize the on-chip RAM before you enable the ECC support to prevent false ECC interrupts triggered by uninitialized bits.

Related Information

System Interconnect on page 7-1
For more information about security, refer to the *Interconnect* chapter.

Functional Description of the On-Chip RAM

The on-chip RAM serves as a general-purpose memory accessible from the FPGA.

The on-chip RAM uses an 64-bit slave interface. The slave interface supports transfers between memory and the NIC-301 L3 interconnect. All reads and writes are serviced in order.

Related Information

- Clock Manager on page 2-1
  For more information about the operating frequency and maximum throughput, refer to the *Clock Manager* chapter.
- Reset Manager on page 3-1

Clocks

The on-chip RAM is driven by the `l3_main_clk` interconnect clock.

The on-chip RAM uses an 64-bit slave interface. The slave interface supports transfers between memory and the NIC-301 L3 interconnect. All reads and writes are serviced in order.

Resets

The contents of the RAM remain unchanged on a cold or warm reset. Reset only clears the state associated with the slave interface.

The on-chip RAM reset is driven by the `onchip_ram_rst_n` interconnect reset.

On-Chip RAM Initialization

You must initialize the on-chip RAM before you enable the ECC. Failure to do so triggers spurious interrupts.

Initialize the on-chip RAM using the following steps:

1. Disable ECC interrupts
2. Enable ECC generation
3. Initialize memory by clearing the contents by writing 0x0 in the address space
4. Enable ECC interrupts

Boot ROM

This section describes hardware aspects of the HPS boot ROM.

Related Information

Booting and Configuration Introduction on page 30-1
For more information about the about the boot ROM software, refer to the *Booting and Configuration* appendix.

Features of the Boot ROM

The boot ROM offers the following features:

- 32-bit interface
- 64 KB size
- Single-ported ROM
- Read acceptance of two
- High throughput - read every clock cycle.

Related Information

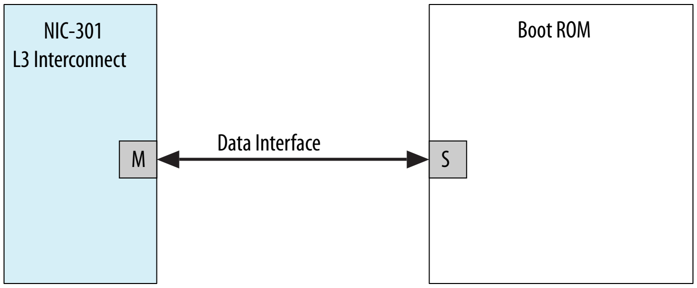
Clock Manager on page 2-1
For more information about the operating frequency and maximum throughput, refer to the *Clock Manager* chapter.

Boot ROM Block Diagram and System Integration

Transfers between memory and the NIC-301 L3 interconnect happen through a 32-bit data interface, gated by the `l3_main_clk` interconnect clock.

The entire RAM is either secure or nonsecure. Security is enforced by the NIC-301 L3 interconnect.

Figure 12-2: Boot ROM Block Diagram



Related Information

System Interconnect on page 7-1
For more information about security, refer to the *Interconnect* chapter.

Functional Description of the Boot ROM

The boot ROM is used only for booting the system. On a cold or warm reset of the microprocessor unit (MPU) subsystem, MPU0 executes the pre-bootloader code stored in the boot ROM.

The boot ROM uses an 32-bit slave interface. The slave interface supports transfers between memory and the NIC-301 L3 interconnect. All writes return an error response.

Clocks

The boot ROM is driven by the `l3_main_clk` interconnect clock.

Resets

The contents of the ROM remain unchanged on a cold or warm reset. Reset only clears the state associated with the slave interface.

The boot ROM reset is driven by the `boot_rom_rst_n` interconnect clock.

NAND Flash Controller 13

2014.07.31

cv_54010 Subscribe Send Feedback

The hard processor system (HPS) provides a NAND flash controller to interface with external NAND flash memory in Altera® system-on-a-chip (SoC) FPGA systems. You can use external flash memory to store a processor boot image, software, or as extra storage capacity for large applications or user data. The HPS NAND flash controller is based on the Cadence® Design IP® NAND Flash Memory Controller.

NAND Flash Controller Features

The NAND flash controller provides the following functionality and features:

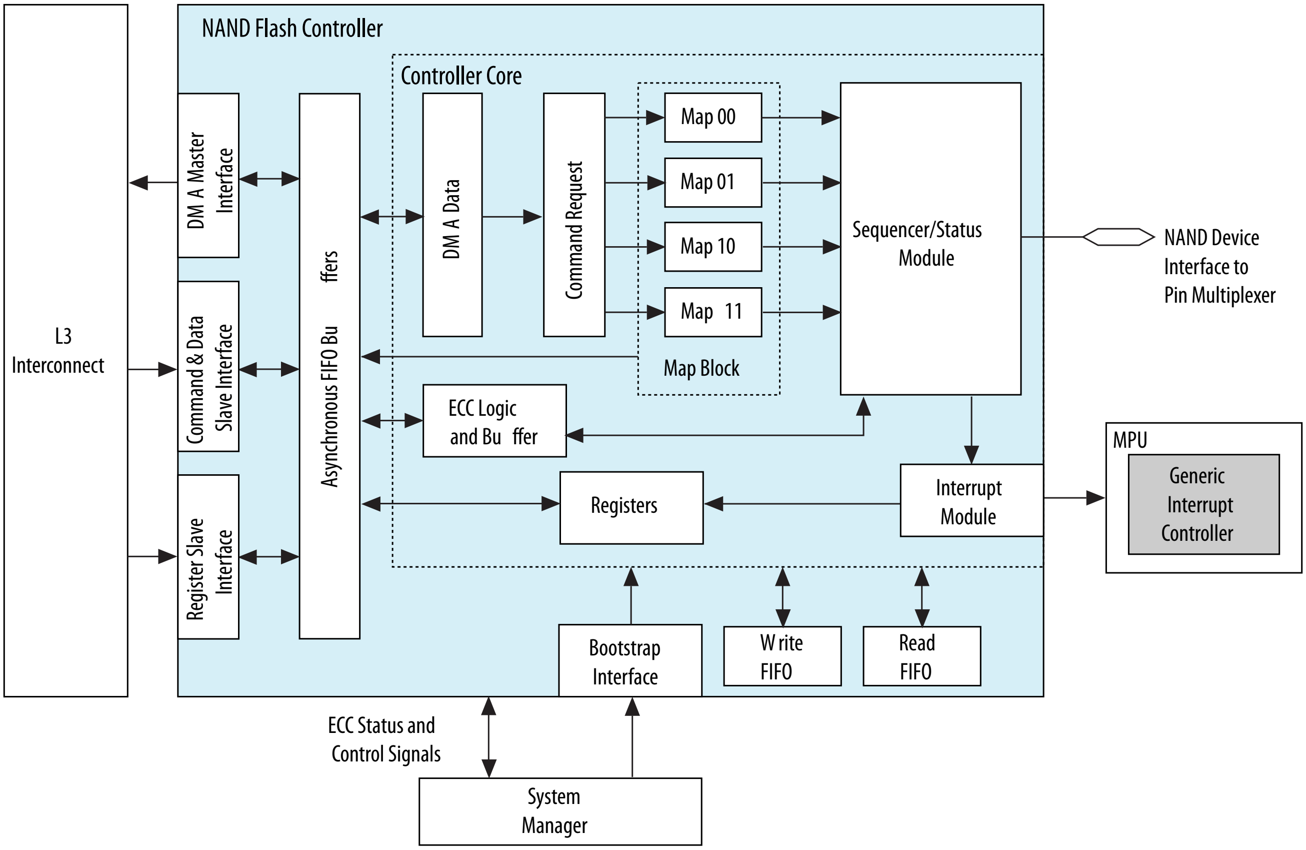
- Supports one x8 NAND flash device
- Supports Open NAND Flash Interface (ONFI) 1.0
- Supports NAND flash memories from Hynix, Samsung, Toshiba, Micron, and ST Micro
- Supports programmable 512 byte (4-, 8-, or 16-bit correction) or 1024 byte (24-bit correction) error correction code (ECC) sector size
- Supports pipeline read-ahead and write commands for enhanced read/write throughput
- Supports devices with 32, 64, 128, 256, 384, or 512 pages per block
- Supports multiplane devices
- Supports page sizes of 512 bytes, 2 kilobytes (KB), 4 KB, or 8 KB
- Supports single-level cell (SLC) and multi-level cell (MLC) devices with programmable correction capabilities
- Provides internal direct memory access (DMA)
- Provides programmable access timing

NAND Flash Controller Block Diagram and System Integration

The flash controller receives commands and data from the host through the command and data slave interface. The host accesses the flash controller’s control and status registers (CSRs) through the register slave interface. The flash controller handles all command sequencing and flash device interactions. The bootstrap interface supports configuration of the NAND flash controller when booting the HPS from NAND flash memory. The flash controller generates interrupts to the HPS Cortex-A9 MPCore™ processor generic interrupt controller. The DMA master interface provides accesses to and from the flash controller through the controller's built-in DMA.

Figure 13-1: NAND Flash Controller Block Diagram

The following figure shows integration of the NAND flash controller in the HPS.



Functional Description of the NAND Flash Controller

This section describes the functionality of the NAND flash controller.

Discovery and Initialization

The NAND flash controller requires a specific initialization sequence after the HPS receives power and the flash device is stable. During initialization, the flash controller queries the flash device and configures itself according to one of the following flash device types:

- ONFI 1.0 compliant devices
- Legacy (non-ONFI) NAND devices

The NAND flash controller identifies ONFI-compliant connected devices using ONFI discovery protocol, by sending the `Read Electronic Signature` command. For devices that do not recognize this command (especially for 512-byte page size devices), software must write to the system manager to assert the `bootstrap_512B_device` signal to identify the device type before reset is de-asserted.

To support booting and initialization, the `rdy_busy_in` pin must be connected. The NAND flash controller sends the `reset` command to the connected device.

The NAND flash controller performs the following initialization steps:

1. If the system manager is asserting `bootstrap_inhibit_init`, the flash controller goes directly to step 7.
2. When the device is ready, the flash controller sends the `ONFI Read ID` command to read the ONFI signature from the memory device, to determine whether an ONFI or a legacy device is connected.
3. If the data returned by the memory device has an ONFI signature, the flash controller then reads the device parameter page. The flash controller stores the relevant device feature information in internal memory control registers, enabling it to correctly program other registers in the flash device, and goes to step 5.
4. If the data does not have a valid ONFI signature, the flash controller assumes that it is a legacy (non-ONFI) device. The flash controller then performs the following steps:

   a. Sends the `reset` command to the device
   b. Reads the device signature information
   c. Stores the relevant values into internal memory controller registers
5. The flash controller resets the memory device. At the same time, it verifies the width of the memory interface. The HPS supports one 8-bit NAND flash device. As a result, the flash controller always detects an 8-bit memory interface.
6. The flash controller sends the `Page Load` command to block 0, page 0 of the device, configuring direct read access, so the processor can boot from that page. The processor can start reading from the first page of the flash memory, which is the expected location of the pre-loader software.

   Note: The system manager can bypass this step by asserting `bootstrap_inhibit_b0p0_load` before reset is de-asserted.
7. The flash controller sends the `reset` command to the flash.
8. The flash controller sets the value of the `rst_comp` bit in the `intr_status0` register in the `status` group.

Bootstrap Interface

The NAND flash controller provides a bootstrap interface that allows software to override the default behavior of the flash controller. The bootstrap interface contains four bits, which when set appropriately, allows the flash controller to skip the initialization phase and begin loading from flash memory immediately after reset. These bits are driven by software through the system manager. They are sampled by the NAND flash controller when the controller is released from reset.

Related Information

System Manager on page 5-1
For more information about the bootstrap interface control bits.

Bootstrap Setting Bits

The following table lists the relevant bootstrap setting bits, found in the system manager's `bootstrap` register, in the `nandgrp` group. This table also lists recommended bootstrap settings for a 512-byte page device.

Table 13-1: Bootstrap Setting Bits

Register	Value
`noinit`	1[22]
`page512`	1
`noloadb0p0`	1
`tworowaddr`	• 1—flash device supports two-cycle addressing • 0—flash device support three-cycle addressing

Related Information

Configuration by Host on page 13-4

Configuration by Host

If the system manager sets `bootstrap_inhibit_init` to 1, the NAND flash controller does not perform the discovery and initialization process. In this case, the host processor must configure the flash controller.

When performance is not a concern in the design, the timing registers can be left unprogrammed.

Related Information

Bootstrap Setting Bits on page 13-3
For recommended configuration-by-host settings to enable the basic read, write, and erase operations for a single-plane, 512 bytes/page device.

Recommended Bootstrap Settings for 512-Byte Page Device

Table 13-2: Recommended Bootstrap Settings for 512-Byte Page Device

Register[23]	Value
`devices_connected`	1
`device_width`	0 indicating an 8-bit NAND flash device
`number_of_planes`	1 indicating a single-plane device
`device_main_area_size`	The value of this register must reflect the flash device's page main area size.
`device_spare_area_size`	The value of this register must reflect the flash device's page spare area size.

[22] When this register is set, the NAND flash controller expects the host to program the related device parameter registers. For more information, refer to *Configuration by Host*.

[23] All registers are in the `config` group.

Register[23]	Value
`pages_per_block`	The value of this register must reflect number of pages per block in the flash device.

NAND Page Main and Spare Areas

Each NAND page has a main area and a spare area. The main area is intended for data storage. The spare area is intended for ECC and maintenance data, such as wear leveling information. Each block consists of a group of pages.

The sizes of the main and spare areas, and the number of blocks in a page, depend on the specific NAND device connected to the NAND flash controller. Therefore, the device-dependent registers, `device_main_area_size`, `device_spare_area_size`, and `pages_p er_block`, must be programmed to match the characteristics of the device.

If your software does not perform the discovery and initialization sequence, the software must include an alternative method to determine the correct value of the device-dependent registers. The HPS boot ROM code enables discovery and initialization by default (that is, `bootstrap_inhibit_init = 0`).

Clocks

Table 13-3: Clock Inputs to NAND Flash Controller

Clock Signal	Description
`nand_x_clk`	Clock for master and slave interfaces and the ECC sector buffer
`nand_clk`	Clock for the NAND flash controller

The frequency of `nand_x_clk` is four times the frequency of `nand_clk`.

For more information about the clock inputs, refer to the *Clock Manager* chapter in the *Cyclone V Device Handbook, Volume 3*.

Related Information

Clock Manager on page 2-1

Resets

The NAND flash controller has one reset signal, `nand_flash_rst_n`. The reset manager drives this signal to the NAND flash controller on a cold or warm reset.

Before the NAND flash controller comes out of the reset state, the pin multiplexers for the flash external interface must be configured.

For more information about the reset manager, refer to the *Reset Manager* chapter in the *Cyclone V Device Handbook, Volume 3*.

Related Information

Reset Manager on page 3-1

[23] All registers are in the `config` group.

Indexed Addressing

The NAND flash controller uses indexed addressing to reduce the address span consumed by the flash controller.

Indirect addressing is controlled by two registers, accessed through the command and data slave interface in the `nanddata` map, as described in *Register Map for Indexed Addressing*.

Related Information

Register Map for Indexed Addressing on page 13-6

Register Map for Indexed Addressing

Table 13-4: Register Map for Indexed Addressing

Register Name	Offset Address	Usage
`Control`	0x0	Software writes the 32-bit control information consisting of MAP command type, block, and page address. The upper four bits must be set to 0. For specific usage of the `Control` register, refer to *MAP00 Address Mapping*, *MAP01 Address Mapping*, *MAP10 Address Mapping*, and *MAP10 Operations*.
`Data`	0x10	The `Data` register is a page-size window into the NAND flash. By reading from or writing to locations starting at this offset, the software reads directly from or writes directly to the page and block of NAND flash memory specified by the `Control` register.

Related Information

- MAP01 Address Mapping on page 13-8
- MAP10 Address Mapping on page 13-10
- MAP10 Operations on page 13-10

Indexed Addressing Host Usage

The host uses indexed addressing as follows:

1. Program the 32-bit index-address field into the `Control` register at offset 0x0 of the data/command slave port. This action provides the flash address parameters to the NAND flash controller.
2. Perform a 32-bit read or write in the `Data` register at offset 0x10 of the data/command slave port.
3. Perform additional 32-bit reads and writes if they are in the same page and block in flash memory.

It is unnecessary to write to the control register for every data transfer if a group of data transfers targets the same page and block address. For example, you can write the control register at the beginning of a page with the block and page address, and then read or write the entire page by directing consecutive transactions to the `Data` register.

Command Mapping

The NAND flash controller supports several flash controller-specific MAP commands, providing an abstraction level for programming a NAND flash device. By using the MAP commands, you can avoid directly programming device-specific commands. Using this abstraction layer provides enhanced performance. Commands take multiple cycles to send off-chip. The MAP commands let you initiate commands and let the flash controller sequence them off-chip to the NAND device.

The NAND flash controller supports the following flash controller-specific MAP commands:

- MAP00 Commands—boot-read or buffer read/write during read-modify-write operations
- MAP01 Commands—memory arrays read/write
- MAP10 Commands—NAND flash controller commands
- MAP11 Commands—low-level direct access

Related Information

- **MAP00 Commands** on page 13-7
- **MAP01 Commands** on page 13-8
- **MAP10 Commands** on page 13-9
- **MAP11 Commands** on page 13-11

MAP00 Commands

MAP00 commands access a page buffer in the NAND flash device. Addressing always begins at 0x0 and extends to the page size specified by the `device_main_area_size` and `device_spare_area_size` registers in the `config` group. You can use this command to perform a boot read. Use MAP00 commands in read-modify-write (RMW) operations to read or write any word in the buffer. MAP00 commands allow a direct data path to the page buffer in the device.

The host can access the page buffer directly using the MAP00 commands only if there are no other MAP01 or MAP10 commands active on the NAND flash controller.

Related Information

MAP00 Address Mapping on page 13-7

MAP00 Address Mapping

Table 13-5: MAP00 Address Mapping

Address Bits	Name	Description
31:28	(reserved)	Set to 0
27:26	`CMD_MAP`	Set to 0
25:13	(reserved)	Set to 0
12:2	`BUFF_ADDR`	Data width-aligned buffer address on the memory device. Maximum page access is 8 KB.
1:0	(reserved)	Set to 0

MAP00 Usage Limitations

The usage of this command under normal operations is limited to the following situations:

- It can be used to perform an Execute-in-Place (XIP) boot from the device; reading directly from the page buffer while booting directly from the device.
- MAP00 commands can be used to perform RMW operations where MAP00 writes are used to modify a read page in the device page buffer. Because the NAND flash controller does not perform ECC correction during such an operation, Altera does not recommend this method in an MLC device.
- In association with MAP11 commands, MAP00 commands provide a way for the host to directly access the device bypassing the hardware abstractions provided by NAND flash controller with MAP01 and MAP10 commands. This method is also used for debugging, or for issuing an operation that the flash controller might not support with MAP01 or MAP10 commands.

Restrictions:

- MAP00 commands cannot be used with MAP01 commands to read part of a page. Accesses using MAP01 commands must perform a complete page transfer.
- No ECC is performed during a MAP00 data access.
- DMA must be disabled (the `flag` bit of the `dma_enable` register in the `dma` group must be set to 0) while performing MAP00 operations.

MAP01 Commands

MAP01 commands transfer complete pages between the host memory and a specific page of the NAND flash device. Because the NAND flash controller supports only page addresses, the entire page must be read or written at once. The actual number of commands required depends on the size of the data transfer. You must use the same address until the entire page is transferred, even if multiple commands are required.

When the NAND flash controller receives a read command, it issues a load operation on the device, waits for the load to complete, and then returns read data. Read data must be read from the start of the page to the end of the page. Write data must be written from the start of the page to the end of the page.

When the NAND flash controller receives confirmation of the transfer, it issues commands to program the data into the device. The flash controller ignores the byte enables for read and write commands and transfers the entire data width.

MAP01 Address Mapping on page 13-8

MAP01 Address Mapping

Table 13-6: MAP01 Address Mapping

Address Bits	Name	Description
31:28	(reserved)	Set to 0
27:26	`CMD_MAP`	Set to 1
25:24	(reserved)	Set to 0
23:<*M*> [24]	`BLK_ADDR`	Block address in the device

Address Bits	Name	Description
(<*M*>-1):0 [24]	`PAGE_ADDR`	Page address in the device

ECC

The NAND flash controller incorporates ECC on-the-fly correction that corrects data read from the device internally before transferring the data out from the flash controller. The ECC sector buffers store data, while the ECC engine computes the error location.

MAP01 Command Usage

Use the MAP01 command as follows:

- A complete page must be read or written using a MAP01 command. During such transfers, every transaction from the host must have the same block and page address. The NAND flash controller internally keeps track of how much of data it reads or writes.
- MAP00 commands cannot be used in between using MAP01 commands for reading or writing a page.
- DMA must be disabled (the `flag` bit of the `dma_enable` register in the `dma` group must be set to 0) while the host is performing MAP01 operations directly. If the host issues MAP01 commands to the NAND flash controller while DMA is enabled, the flash controller discards the request and generates an `unsup_cmd` interrupt.

MAP10 Commands

MAP10 commands provide an interface to the control plane of the NAND flash controller. MAP10 commands control special functions of the flash device, such as erase, lock, unlock, copy back, and page spare area access. Data passed in this command pathway targets the NAND flash controller rather than the flash device. Unlike other command types, the data (input or output) related to these transactions does not affect the contents of the flash device. Rather, this data specifies and performs the exact commands of the flash controller. Only the lower 16 bits of the `Data` register contain the relevant information.

Related Information

MAP10 Address Mapping on page 13-10

[24] <*M*> depends on the number of pages per block in the device. <*M*> = ceil(log2(<*device pages per block*>)) . Therefore, use the following values:

32 pages per block: <*M*>=5

64 pages per block: <*M*>=6

128 pages per block: <*M*>=7

256 pages per block: <*M*>=8

384 pages per block: <*M*>=9

512 pages per block: <*M*>=9

MAP10 Address Mapping

Table 13-7: MAP10 Address Mapping

Address Bits	Name	Description
31:28	(reserved)	Set to 0
27:26	`CMD_MAP`	Set to 2
25:24	(reserved)	Set to 0
23:<M>[25]	`BLK_ADDR`	Block address in the device
(<M>-1):0[25]	`PAGE_ADDR`	Page address in the device

MAP10 Operations

Table 13-8: MAP10 Operations

Command	Function
0x01	Sets block address for erase and initiates operation
0x10	Sets unlock start address
0x11	Sets unlock end address and initiates unlock
0x21	Initiates a lock of all blocks
0x31	Initiates a lock-tight of all blocks
0x41	Sets up for spare area access
0x42	Sets up for default area access

[25] <*M*> depends on the number of pages per block in the device. <*M*> = ceil(log2(<*device pages per block*>)) . Therefore, use the following values:

32 pages per block: <*M*>=5

64 pages per block: <*M*>=6

128 pages per block: <*M*>=7

256 pages per block: <*M*>=8

384 pages per block: <*M*>=9

512 pages per block: <*M*>=9

Command	Function
0x43	Sets up for main+spare area access
0x60	Loads page to the buffer for a RMW operation
0x61	Sets the destination address for the page buffer in RMW operation
0x62	Writes the page buffer for a RMW operation
0x1000	Sets copy source address
0x11<*PP*>	Sets copy destination address and initiates a copy of <*PP*> pages
0x20<*PP*>	Sets up a pipeline read-ahead of <*PP*> pages
0x21<*PP*>	Sets up a pipeline write of <*PP*> pages

MAP10 Command Usage

Use the MAP10 command as follows:

- MAP10 commands should be used to issue commands to the device, such as erase, copy-back, lock, or unlock.
- MAP10 pipeline commands should also be used to read or write consecutive multiple pages from the flash device within a device block boundary. The host must first issue a MAP10 pipeline read or write command and then issue MAP01 commands to do the actual data transfers. The MAP10 pipeline read or write command instructs the NAND flash controller to use high-performance commands such as cache or multiplane because the flash controller has knowledge of multiple consecutive pages to be read. The pages must not cross a block boundary. If a block boundary is crossed, the flash controller generates an unsupported command (`unsup_cmd`) interrupt and drops the command.
- Up to four pipeline read or write commands can be issued to the NAND flash controller.
- While the NAND flash controller is performing MAP10 pipeline read or write commands, DMA must be disabled (the `flag` bit of the `dma_enable` register in the `dma` group must be set to 0). DMA must be disabled because the host is directly transferring data from and to the flash device through the flash controller.

MAP11 Commands

MAP11 commands provide direct access to the NAND flash controller's address and control cycles, allowing software to issue the commands directly to the flash device using the `Command` and `Data` registers. The MAP11 command is useful if the flash device supports a device-specific command not supported by standard flash commands. It can also be useful for low-level debugging.

MAP11 commands provide a direct control path to the flash device. These commands execute command, address, and data read/write cycles directly on the NAND device interface. Command, address, and write data values are placed in the `Data` register. On a read, the returned data also appears in the `Data` register. The indirect address register encodes the control operation type. Command and address cycles to the device must be a write transaction on the host bus. For data cycles, the type of transaction on the host bus (read/write) determines the data cycle type on the device interface. The host can issue only single-beat accesses to the data slave port while using MAP11 commands.

Related Information

MAP11 Addressing Mapping on page 13-12

MAP11 Addressing Mapping

Table 13-9: MAP11 Addressing Mapping

Address Bits	Name	Description
31:28	(reserved)	Set to 0
27:26	`CMD_MAP`	Set to 3
25:2	(reserved)	Set to 0
1:0	`TYPE`	Sets the control type as follows: • 0 = Command cycle • 1 = Address cycle • 2 = Data Read/Write Cycle

MAP11 Command Usage

Use the MAP11 command as follows:

- Use MAP11 commands only in special cases, for debugging or sending device-specific commands that are not supported by the NAND flash controller.
- DMA must be disabled before you use MAP11 operations.
- The host can use only single beat access transfers when using MAP11 commands.

Note: MAP11 commands provide direct, unstructured access to the NAND flash device. Incorrect use can lead to unpredictable behavior.

Data DMA

The DMA transfers data with minimal host involvement. Software initiates data DMA with the MAP10 command.

The `flag` bit of the `dma_enable` register in the `dma` group enables data DMA functionality. Only enable or disable this functionality when there are no active transactions pending in the NAND flash controller. When the DMA is enabled, the flash controller initiates one DMA transfer per MAP10 command over the DMA master interface. When the DMA is disabled, all operations with the flash controller occur through the data/command slave interface.

The NAND flash controller supports up to four outstanding DMA commands, and ignores additional DMA commands. If software issues more than four outstanding DMA commands, the flash controller issues the `unsup_cmd` interrupt. On receipt of a DMA command, the flash controller performs command sequencing to transfer the number of pages requested in the DMA command. The DMA master reads or writes page data from the system memory in programmed burst-length chunks. After the DMA command completes, the flash controller issues an interrupt, and starts working on the next queued DMA command.

Pipelining allows the NAND flash controller to optimize its performance while executing back-to-back commands of the same type.

With certain restrictions, non-DMA MAP10 commands can be issued to the NAND flash controller while the flash controller is servicing DMA transactions. MAP00, MAP01, and MAP11 commands cannot be issued while DMA mode is enabled because the flash controller is operating in an extremely tightly-coupled, high-performance data transfer mode. On receipt of erroneous commands (MAP00, MAP01 or MAP11), the flash controller issues an `unsup_cmd` interrupt to inform the host about the violating command.

When the host issues a data DMA command, the NAND flash controller transfers data between the flash device and host memory if data DMA is enabled (the `flag` bit of the `dma_enable` register in the `dma` group is set to 1). On the completion of the transfer the flash controller informs the host by asserting an interrupt.

- A data DMA command is a type of MAP10 command. This command is interpreted by the data DMA engine and not by the flash controller core.
- No MAP01, MAP00, or MAP11 commands are allowed when DMA is enabled.
- Before the flash controller can accept data DMA commands, DMA must be enabled by setting the `flag` bit of the `dma_enable` register in the `dma` group.
- When DMA is enabled and the DMA engine initiates data transfers, ECC can be enabled for as-needed data correction concurrent with the data transfer.
- MAP10 commands are used along with data movements similar to MAP01 commands.
- With the exception of data DMA commands and MAP10 pipeline read and write commands, all other MAP10 commands such as erase, lock, unlock, and copy-back are forwarded to the flash controller.
- At any time, up to four outstanding data DMA commands can be handled by flash controller. During multi-page operations, the DMA transfer must not cross a flash block boundary. If it does, the flash controller generates an unsupported command (`unsup_cmd`) interrupt and drops the command.
- Data DMA commands are typically multi-page read and write commands with an associated pointer in host memory. The multi-page data is transferred to or from the host memory starting from the host memory pointer.
- Data DMA uses the `flash_burst_length` register in the `dma` group to determine the burst length value to drive on the interconnect. The data DMA hardware does not account for the interconnect's boundary crossing restrictions. The host must initialize the starting host address so that the DMA master burst does not cross a 4 KB boundary.

There are two methods for initiating a DMA transaction: the multitransaction DMA command, and the burst DMA command.

Multitransaction DMA Command

The NAND flash controller processes multitransaction DMA commands only if it receives all four command-data pairs in order. The flash controller responds to out-of-order commands with an `unsup_cmd` interrupt. The flash controller also responds with an `unsup_cmd` interrupt if sequenced commands are interleaved with other flash controller MAP commands.

To initiate DMA with a multitransaction DMA command, you send four command-data pairs to the NAND flash controller's data and control slave port, as shown in *Command-Data Pair Formats*.

Using Multitransaction DMA Commands

If you want the NAND flash controller DMA to perform cacheable accesses then you must configure the cache bits by writing the `l3master` register in the `nandgrp` group in the system manager. The NAND flash controller DMA must be idle before you use the system manager to change its cache capabilities.

You can issue non-DMA MAP10 commands while the NAND flash controller is in DMA mode. For example, you might trigger a host-initiated page move between DMA commands, to achieve wear leveling. However, do not interleave non-DMA MAP10 commands between the command-data pairs in a set of multitransaction DMA commands. You must issue all four command-data pairs shown in the above tables before sending a different command.

Note: Do not issue MAP00, MAP01 or MAP11 commands while DMA is enabled.

MAP10 commands in multitransaction format are written to the `Data` register at offset 0x10 in `nanddata`, the same as MAP10 commands in increment four (INCR4) format (described in *Burst DMA Command*).

Related Information

- **Indexed Addressing** on page 13-6
- **Burst DMA Command** on page 13-15
- **System Manager** on page 5-1

Burst DMA Command

You can initiate a DMA transfer by sending a command to the NAND flash controller as a burst transaction of four 16-bit accesses. This form of DMA command might be useful for initiating DMA transfers from custom IP in the FPGA fabric. Most processor cores cannot use this form of DMA command, because they cannot control the width of the burst.

When DMA is enabled, the NAND flash controller recognizes the MAP10 pipeline DMA command as an INCR4 command, in the format shown in the following table. The address decoding for MAP10 pipeline DMA command remains the same, as shown in *MAP10 Address Mapping*.

[29] INT specifies the host interrupt to be generated at the end of the complete DMA transfer. INT controls the value of the `dma_cmd_comp` bit of the `intr_status0` register in the `status` group at the end of the DMA transfer. INT can take on one of the following values:

0—Do not interrupt host. The `dma_cmd_comp` bit is set to 0.

1—Interrupt host. The `dma_cmd_comp` bit is set to 1.

MAP10 commands in INCR4 format are written to the `Data` register at offset 0x10 in `nanddata`, the same as MAP10 commands in multitransaction format (described in *Multitransaction DMA Command*).

Table 13-14: MAP10 Burst DMA (INCR4) Command Structure

The following table lists the MAP10 burst DMA command structure. The burst DMA command carries the same information as the multi-transaction DMA command-data pairs, but in a very different format.

Data Beat	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Beat 0	0x2				0x0: read. 0x1: write.				<*PP*>=number of pages							
Beat 1 [30]	Memory address high															
Beat 2 [30]	Memory address low															
Beat 3	0x0							INT[31]	Burst length							

You can optionally send the 16-bit fields in the above table to the NAND flash controller as four separate bursts of length 1 in sequential order. Altera recommends this method.

If you want the NAND flash controller DMA to perform cacheable accesses, you must configure the cache bits by writing the `l3master` register in the `nandgrp` group in the system manager. The NAND flash controller DMA must be idle before you use the system manager to modify its cache capabilities.

ECC

The NAND flash controller incorporates ECC logic to calculate and correct bit errors. The flash controller uses a Bose-Chaudhuri-Hocquenghem (BCH) algorithm for detection of multiple errors in a page.

The NAND flash controller supports 512- and 1024-byte ECC sectors. The flash controller inserts ECC check bits for every 512 or 1024 bytes of data, depending on the selected sector size. After 512 or 1024 bytes, the flash controller writes the ECC check bit information to the device page.

ECC information is striped in between 512 or 1024 bytes of data across the page. The NAND flash controller reads ECC information in the same pattern and the presence of errors is calculated according to 512 or 1024 bytes of data read.

[30] The buffer address in host memory, which must be aligned to 32 bits

[31] INT specifies the host interrupt to be generated at the end of the complete DMA transfer. INT controls the value of the `dma_cmd_comp` bit of the `intr_status0` register in the `status` group at the end of the DMA transfer. INT can take on one of the following values:

0—Do not interrupt host. The `dma_cmd_comp` bit is set to 0.

1—Interrupt host. The `dma_cmd_com p` bit is set to 1.

Correction Capability, Sector Size, and Check Bit Size

Table 13-15: Correction Capability, Sector Size, and Check Bit Size

Correction	Sector Size in Bytes	Check Bit Size in Bytes
4	512	8
8	512	14
16	512	26
24	1024	46

ECC Programming Modes

The NAND flash controller provides the following ECC programming modes that software uses to format a page:

- Main Area Transfer Mode
- Spare Area Transfer Mode
- Main+Spare Area Transfer Mode

Related Information

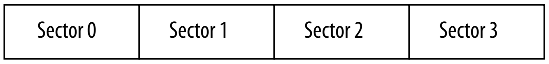
- **Main Area Transfer Mode** on page 13-17
- **Spare Area Transfer Mode** on page 13-17
- **Main+Spare Area Transfer Mode** on page 13-18

Main Area Transfer Mode

In main area transfer mode, when ECC is enabled, the NAND flash controller inserts ECC check bits in the data stream on writes and strips ECC check bits on reads. Software does not need to manage the ECC sectors when writing a page. ECC checking is performed by the flash controller, so software simply transfers the data.

If ECC is turned off, the NAND flash controller does not read or write ECC check bits.

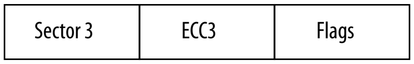
Figure 13-2: Main Area Transfer Mode Programming Model for ECC



Spare Area Transfer Mode

The NAND flash controller does not introduce or interpret ECC check bits in spare area transfer mode, and acts as a pass-through for data transfer.

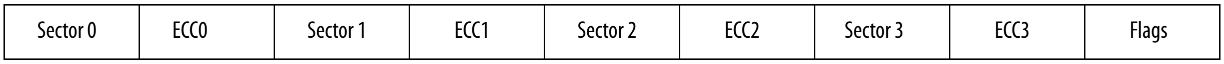
Figure 13-3: Spare Area Transfer Mode Programming Model for ECC



Main+Spare Area Transfer Mode

In main+spare area transfer mode, the NAND flash controller expects software to format a page as shown in following figure. When ECC is enabled during a write operation, the flash controller-generated ECC check bits replace the ECC check bit data provided by software. During read operations, the flash controller forwards the ECC check bits from the device to the host. If ECC is disabled, page data received from the software is written to the device, and read data received from the device is forwarded to the host.

Figure 13-4: Main+Spare Area Transfer Mode Programming Model for ECC



Sector 0	ECC0	Sector 1	ECC1	Sector 2	ECC2	Sector 3	ECC3	Flags

Preserving Bad Block Markers

When flash device manufacturers test their devices at the time of manufacture, they mark any bad device blocks that are found. Each bad block is marked at specific, known offsets, typically at the base of the spare area. A bad block marker is any byte value other than 0xFF (the normal state of erased flash).

Bad block markers can be overwritten by the last sector data in a page when ECC is enabled. This happens because the NAND flash controller also uses the main area of a page to store ECC information, which causes the last sector to spill over into the spare area. It is necessary for the system to preserve the bad block information prior to writing data, to ensure the correct identification of bad blocks in the flash device.

You can configure the NAND flash controller to skip over a specified number of bytes when it writes the last sector in a page to the spare area. This option allows the flash controller to preserve bad block markers. To use this option, write the desired offset to the `spare_area_skip_bytes` register in the `config` group. For example, if the device page size is 2 KB, and the device manufacturer stores the bad block markers in the first two bytes in the spare area, set the `spare_area_skip_bytes` register to 2. When the flash controller writes the last sector of the page that overlaps with the spare area, it starts at offset 2 in the spare area, skipping the bad block marker at offset 0. A value of 0 (default) specifies that no bytes are skipped. The value of `spare_area_skip_bytes` must be an even number. For example, if the bad block marker is a single byte, set `spare_area_skip_bytes` to 2.

In main area transfer mode, the NAND flash controller does not skip the bad block marker. Instead, it overrides the bad block marker with the value programmed in the `spare_area_marker` register in the `config` group. This 8-bit register is used in conjunction with the `spare_area_skip_bytes` register in the `config` group to determine which bytes in the spare area of a page should be written with a the new marker value. For example, to mark a block as good set the `spare_area_marker` register to 0xFF and set the `spare_area_skip_bytes` register to the number of bytes that the marker should be written to, starting from the base of the spare area.

In the spare area transfer mode, the NAND flash controller ignores the `spare_area_skip_bytes` and `spare_area_marker` registers. The flash controller transfers the data exactly as received from the host or device.

In the main+spare area transfer mode, the NAND flash controller starts writing the last sector in a page into the spare area, starting at the offset specified in the `spare_area_skip_bytes` register. However, the area containing the bad block identifier information is overwritten by the data the host writes into the page. The host writes both the data sectors and the bad block markers. The flash controller depends on the host software to set up the bad block markers properly before writing the data.

Figure 13-5: Bad Block Marker

The following figure shows an example of how the NAND flash controller can skip over a bad block marker. In this example, the flash device has a 2-KB page with a 64-byte spare area. A 14-byte sector ECC is shown, with 8 byte per sector correction.

Error Correction Status

The ECC error correction information (ECCCorInfo_b01) register, in the ecc group, contains error correction information for each read or write that the NAND flash controller performs. The ECCCorInfo_b01 register contains ECC error correction information in the max_errors_b0 and uncor_err_b0 fields.

At the end of data correction for the transaction in progress, ECCCorInfo_b01 holds the maximum number of corrections applied to any ECC sector in the transaction. In addition, this register indicates whether the transaction as a whole has correctable errors, uncorrectable errors, or no errors at all. A transaction has no errors when none of the ECC sectors in the transaction has any errors. The transaction is marked as uncorrectable if any one of the sectors is uncorrectable. The transaction is marked as correctable if any one sector has correctable errors and none is uncorrectable.

At the end of each transaction, the host must read this register. The value of this register provides data to the host about the block. The host can take corrective action after the number of correctable errors encountered reaches a particular threshold value.

Interface Signals

Table 13-16: NAND Flash Interface Signals

As listed in the following table, the HPS I/O pins support a single x8 device.

Signal	Width	I/O	Description
ad	8	in/out	Command, address and data for the flash device

Signal	Width	I/O	Description
`ale`	1	out	Address latch enable
`ce_n`	1	out	Output Active-low chip enable
`cle`	1	out	Command latch enable
`re_n`	1	out	Active-low read enable signal
`rb`	1	in	Ready/busy signal
`we_n`	1	out	Active-low write enable signal
`wp_n`	1	out	Active-low write protect signal

NAND Flash Controller Programming Model

This section describes how the NAND flash controller is to be programmed by software running on the microprocessor unit (MPU).

Note: If you write a configuration register and follow it up with a data operation that is dependent on the value of this configuration register, Altera recommends that you read the value of the register before performing the data operation. This read operation ensures that the posted write of the register is completed and takes effect before the data operation is issued to the NAND flash controller.

Basic Flash Programming

This section describes the steps that must be taken by the software to access and control the NAND flash controller.

NAND Flash Controller Optimization Sequence

The software must configure the flash device for interrupt or polling mode, using the `bank0` bit of the `rb_pin_enabled` register in the `config` group. If the device is in polling mode, the software must also program the additional registers, to select the times and frequencies of the polling. Program the following registers in the `config` group:

- Set the `rb_pin_enabled` register to the desired mode of operation for each flash device.
- For polling mode, set the `load_wait_cnt` register to the appropriate value depending on the speed of operation of the NAND flash controller, and the desired wait value.
- For polling mode, set the `program_wait_cnt` register to the appropriate value by software depending on the speed of operation of the NAND flash controller, and the desired wait value.
- For polling mode, set the `erase_wait_cnt` register to the appropriate value by software depending on the speed of operation of the NAND flash controller, and the desired wait value.
- For polling mode, set the `int_mon_cyccnt` register to the appropriate value by software depending on the speed of operation of the NAND flash controller, and the desired wait value.

At any time, the software can change any flash device from interrupt mode to polling mode or vice-versa, using the `bank0` bit of the `rb_pin_enabled` register.

The software must ensure that the particular flash device does not have any outstanding transactions before changing the mode of operation for that particular flash device.

Device Initialization Sequence

At initialization, the host software must program the following registers in the `config` group:

- Set the `devices_connected` register to 1.
- Set the `device_width` register to 8.
- Set the `device_main_area_size` register to the appropriate value.
- Set the `device_spare_area_size` register to the appropriate value.
- Set the `pages_per_block` register according to the parameters of the flash device.
- Set the `number_of_planes` register according to the parameters of the flash device.
- If the device allows two ROW address cycles, the `flag` bit of the `two_row_addr_cycles` register must be set to 1. The host program can ensure this condition either of the following ways:
  - Set the `flag` bit of the `bootstrap_two_row_addr_cycles` register to 1 prior to the NAND flash controller's reset initialization sequence, causing the flash controller to initialize the bit automatically.
  - Set the `flag` bit of the `two_row_addr_cycles` register directly to 1.
- Clear the `chip_enable_dont_care` register in the `config` group to 0.

The NAND flash controller can identify the flash device features, allowing you to initialize the flash controller registers to interface correctly with the device, as described in *Discovery and Initialization*.

However, a few NAND devices do not follow any universally accepted identification protocol. If connected to such a device, the NAND flash controller cannot identify it correctly. If you are using such a device, your software must use other means to ensure that the initialization registers are set up correctly.

Related Information

Discovery and Initialization on page 13-2

Device Operation Control

This section provides a list of registers that you need to program while choosing to use multi-plane or cache operations on the device. If the device does not support multi-plane operations or cache operations, then these registers can be left at their power-on reset values with no impact on the functionality of the NAND flash controller. Even if the device supports these sequences, the software may choose not to use these sequences and can leave these registers at their power-on reset values.

Program the following registers in the `config` group to achieve the best performance from a given device:

- Set `flag` bit in the `multiplane_operation` register in the `config` group to 1 if the device supports multi-plane operations to access the data on the flash device connected to the NAND flash controller. If the flash controller is set up for multi-plane operations, the number of pages to be accessed is always a multiple of the number of planes in the device.
- If the NAND flash controller is configured for multi-plane operation, and if the device has support for multi-plane read command sequence, set the `multiplane_read_enable` register in the `config` group.
- If the device implements multiplane address restrictions, set the `flag` bit in the `multiplane_addr_restrict` register to 1.
- Initialize the `die_mask` and `first_block_of_next_plane` registers as per device requirements.

- If the device supports cache command sequences, enable the cache_write_enable and cache_read_enable registers in the config group.
- Clear the flag bit of the copyback_disable register in the config group to 0 if the device does not support the copyback command sequences. The register defaults to enabled state.
- The read_mode, write_mode and copyback_mode registers, in the config group, currently need not be written by software, because the NAND flash controller is capable of using the correct sequences based on a combination of some multi-plane or cache-related settings of the NAND flash controller and the manufacturer ID. If at some future time these settings change, program the registers to accommodate the change.

ECC Enabling

Before you start any data operation on the flash device, you must decide whether you want the ECC enabled or disabled.

If the ECC needs enabling, set up the appropriate correction level depending on the page size and the spare area available on the device.

Set the flag bit in the ecc_enable register in the config group to 1 to enable ECC. If enabled, the following registers in the config group must be programmed accordingly, else they can be ignored:

- Initialize the ecc_correction register to the appropriate correction level.
- Program the spare_area_skip_bytes and spare_area_marker registers in the config group if the software needs to preserve the bad block marker.

Related Information

ECC on page 13-16
For detailed information about ECCs.

NAND Flash Controller Performance Registers

These registers specify the size of the bursts on the device interface, which maximizes the overall performance on the NAND flash controller.

Initialize the flash_burst_length register in the dma group to a value which maximizes the performance of the device interface by minimizing the number of bursts required to transfer a page.

Interrupt and DMA Enabling

Prior to initiating any data operation on the NAND flash controller, the software must set appropriate interrupt status register bits. If the software chooses to use the DMA logic in the flash controller, then the appropriate DMA enable and interrupts bits in the register space must be set.

1. Set the flag bit in the global_int_enable register in the config group to 1, to enable global interrupt.
2. Set the relevant bits of the intr_en0 register in the status group to 1 before sending any operations if the flash controller is in interrupt mode.
3. Enable DMA if your application needs DMA mode. Enable DMA by setting the flag bit of the dma_enable register in the dma group. Altera recommends that the software reads back this register to ensure that the mode change is accepted before sending a DMA command to the flash controller.
4. If the DMA is enabled, then set up the appropriate bits of the dma_intr_en register in the dma group.

Order of Interrupt Status Bits Assertion

The following interrupt status bits, in the intr_status0 register in the status group, are listed in the order of interrupt bit setting:

1. time_out—All other interrupt bits are set to 0 when the watchdog time_out bit is asserted.
2. dma_cmd_comp—This interrupt status bit is the last to be asserted during a DMA operation to transfer data. This bit signifies the completion of data transfer sequence.
3. pipe_cpybck_cmd_comp—This bit is asserted when a copyback command or the last page of a pipeline command completes.
4. locked_blk—This bit is asserted when a program (or erase) is performed on a locked block.
5. INT_act—No relationship with other interrupt status bits. Indicates a transition from 0 to 1 on the ready_busy pin value for that flash device.
6. rst_comp—No relationship with other interrupt status bits. Occurs after a reset command has completed.
7. For an erase command:
   a. erase_fail (if failure)
   b. erase_comp
8. For a program command:
   a. locked_blk (if performed on a locked block)
   b. pipe_cmd_err (if the pipeline sequence is broken by a MAP01 command)
   c. page_xfer_inc (at the end of each page data transfer)
   d. program_fail (if failure)
   e. pipe_cpybck_cmd_comp
   f. program_comp
   g. dma_cmd_comp (If DMA enabled)
9. For a read command:
   a. pipe_cmd_err (if the pipeline sequence is broken by a MAP01 command)
   b. page_xfer_inc (at the end of each page data transfer)
   c. pipe_cpybck_cmd_comp
   d. load_comp
   e. ecc_uncor_error (if failure)
   f. dma_cmd_comp (If DMA enabled)

Timing Registers

You must optimize the following registers for your flash device's speed grade and clock frequency. The NAND flash controller operates correctly with the power-on reset values. However, functioning with power-on reset values is a non-optimal mode that provides loose timing (large margins to the signals).

Set the following registers in the config group to optimize the NAND flash controller for the speed grade of the connected device and frequency of operation of the flash controller:

- twhr2_and_we_2_re
- tcwaw_and_addr_2_data
- re_2_we
- acc_clks
- rdwr_en_lo_cnt
- rdwr_en_hi_cnt

- max_rd_delay
- cs_setup_cnt
- re_2_re

Registers to Ignore

You do not need to initialize the following registers in the config group:

- The transfer_spare_reg register—Data transfer mode can be initialized using MAP10 commands.
- The write_protect register—Does not need initializing unless you are testing the write protection feature.

Flash-Related Special Function Operations

This section describes all the special functions that can be performed on the flash memory.

The functions are defined by MAP10 commands as described in *Command Mapping*.

Related Information

Command Mapping on page 13-7

Erase Operations

Before data can be written to flash, an erase cycle must occur. The NAND flash memory controller supports single block and multi-plane erases.

The controller decodes the block address from the indirect addressing shown in *MAP10 Address Mapping*.

Related Information

MAP10 Address Mapping on page 13-10

Single Block Erase

A single command is needed to complete a single-block erase, as follows:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the desired erase block.
2. Write 0x01 to the Data register.

For a single block erase, the register multiplane_operation in the config group must be reset.

After device completes erase operation, the controller generates an erase_comp interrupt. If the erase operation fails, the erase_fail interrupt is issued. The failing block's address is updated in the err_block_addr0 register in the status group.

Multi-Plane Erase

For multi-plane erases, the number_of_planes register in the config group holds the number of planes in the flash device, and the block address specified must be aligned to the number of planes in the device. The NAND flash controller consecutively erases each block of the memory, up to the number of planes available. Issue this command as follows:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the desired erase block.
2. Write 0x01 to the Data register.

For multi-plane erase, the register multiplane_operation in the config group must be set.

After the device completes erase operation on all planes, the NAND flash controller generates an erase_comp interrupt. If the erase operation fails on any of the blocks in a multi-plane erase command, an erase_fail interrupt is issued. The failing block's address is updated in the err_block_addr0 register in the status group.

Lock Operations

The NAND flash controller supports the following features:

- Flash locking—The NAND flash controller supports all flash locking operations.

  The flash device itself might have limited support for these functions. If the device does not support locking functions, the flash controller ignores these commands.
- Lock-tight—With the lock-tight feature, the NAND flash controller can prevent lock status from being changed. After the memory is locked tight, the flash controller must be reset before any flash area can be locked or unlocked.

Unlocking a Span of Memory Blocks

To unlock several blocks of memory, perform the following steps:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the starting address of the area to unlock.
2. Write 0x10 to the Data register.
3. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the ending address of the area to unlock.
4. Write 0x11 to the Data register.

When unlocking a range of blocks, the start block address must be less than the end block address. Otherwise, the NAND flash controller exhibits undetermined behavior.

Locking All Memory Blocks

To lock the entire memory:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to any memory address.
2. Write 0x21 to the Data register.

Setting Lock-Tight on All Memory Blocks

After the lock-tight is applied, unlocked areas cannot be locked, and locked areas cannot be unlocked. To lock-tight the entire memory:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to any memory address.
2. Write 0x31 to the Data register.

To disable the lock-tight, reset the memory controller.

Transfer Mode Operations

You can configure the NAND flash controller in one of the following modes of data transfer:

- Default area transfer mode
- Spare area transfer mode
- Main+spare area transfer mode

The NAND flash controller determines the default transfer mode from the setting of transfer_spare_reg register in the config group. Use MAP10 commands to dynamically change the transfer mode from the existing mode to the new mode. All subsequent commands are in the new mode of transfer. You must consider that transfer modes can be changed at logical data transfer boundaries. For example:

- At the beginning or end of a page in case of single page read or write.
- At the beginning or end of a complete multi-page pipeline read or write command.

transfer_spare_reg and MAP10 Transfer Mode Commands

The following table lists the functionality of the MAP10 transfer mode commands, and their mappings to the transfer_spare_reg register in the config group.

Table 13-17: transfer_spare_reg and MAP10 Transfer Mode Commands

transfer_spare_reg	MAP10 Transfer Mode Commands	Resulting NAND Flash Controller Mode
0	0x42	Main[32]
0	0x41	Spare
0	0x43	Main+spare
1	0x42	Main+spare[32]
1	0x41	Spare
1	0x43	Main+spare

Related Information

MAP10 Commands on page 13-9

For detailed information about the MAP10 commands.

Configure for Default Area Access

You only need to configure for default area access if the transfer mode was previously changed to spare area or main+spare area. To configure default area access:

1. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to any block.
2. Write 0x42 to the Data register.

The NAND flash controller determines the default area transfer mode from the setting of the transfer_spare_reg register in the config group. If it is set to 1, then the transfer mode becomes main +spare area, otherwise it is main area.

Configure for Spare Area Access

To access only the spare area of the flash device, use the MAP10 command to set up the NAND flash controller to read or write only the spare area on the device. After the flash controller is set up, use

[32] Default access mode (0x42) maps to either main (only) or main+spare mode, depending on the value of transfer_spare_reg.

MAP01 read and write commands to access the spare area of the appropriate block and page addresses. To configure the NAND flash controller to access the spare area only, perform the following steps:

1. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the target block.
2. Write 0x41 to the `Data` register.

Configure for Main+Spare Area Access

To configure the NAND flash controller to access the main+spare area:

1. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ ADDR` field to the target block.
2. Write 0x43 to the `Data` register.

Read-Modify-Write Operations

To read a specific page or modify a few words, bytes, or bits in a page, use the RMW operations. A read command copies the desired data from flash memory to a page buffer. You can then modify the information in the buffer using MAP00 buffer read and write commands and issue another command to write that information back to the memory.

The read-modify-write command operates on an entire page. This command is also useful for a copy type operation, where most of a page is saved to a new location. In this type of operation, the NAND flash controller reads the data, modifies a specified number of words in the page, and then writes the modified page to a new location.

Note: Because the data is modified within the page buffer of the flash device, the NAND flash controller ECC hardware is not used in RMW operations. Software must update the ECC during RMW operations.

Note: For a read-modify-write command to work with hardware ECC, the entire page must be read into system memory, modified, then written back to flash without relying on the RMW feature.

Read-Modify-Write Operation Flow

1. Start the flow by reading a page from the memory:
   - Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the starting address of the desired block.
   - Write 0x60 to the `Data` register.

   This step makes the page available to you in the page buffer in the flash device.
2. Provide the destination page address:
   - Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the destination address of the desired block.
   - Write 0x61 to the `Data` register.

   This step initiates the page program and provides the destination address to the device.
3. Use the MAP00 page buffer read and write commands to modify the data in the page buffer.
4. Write the page buffer data back to memory:
   - Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the same destination address.
   - Write 0x62 to the `Data` register.

This step performs the write.

After the device completes the load operation, the NAND flash controller issues a `load_comp` interrupt. A `program_comp` interrupt is issued when the host issues the write command and the device completes the program operation.

If the page program operation (as a part of an RMW operation) results in a program failure in the device, `program_fail` interrupt is issued. The failing page's block and page address is updated in the `err_block_addr0` and `err_page_addr0` registers in the `status` group.

Copy-back Operations

The NAND flash controller supports copy back operations. However, the flash device might have limited support for this function. If you attempt to perform a copy-back operation on a device that does not support copy-back, the NAND flash controller triggers an interrupt. An interrupt is also triggered if the source block is not specified before the destination block is specified, or if the destination block is not specified in the next command following a source block specification.

The NAND flash controller cannot do ECC validation in case of copy-back commands. The flash controller copies the ECC data, but does not check it during the copy operation.

Note: Altera recommends that you use copy-back only if the ECC implemented in the flash controller is strong enough so that the next access can correct accumulated errors.

The 8-bit value <*PP*> specifies the number of pages for copy-back. With this feature, the NAND flash controller can copy multiple consecutive pages with a single command. When you issue a copy-back command, the flash controller performs the operation in the background. The flash controller puts other commands on hold until the current copy-back completes.

For a multi-plane device, if the `flag` bit in the `multiplane_operation` register in the `config` group is set to 1, multi-plane copy-back is available as an option. In this case, the block address specified must be plane-aligned and the value <*PP*> must specify the total number of pages to copy as a multiple of the number of planes. The block address continues incrementing, keeping the page address fixed, for the total number of planes in the device before incrementing the page address.

A `pipe_cpyba ck_cmd_comp` interrupt is generated when the flash controller has completed copy-back operation of all <*PP*> pages. If any page program operation (as a part of copy back operation) results in a program failure in the device, the `program_fail` interrupt is issued. The failing page's block and page address is updated in the `err_block_addr0` and `err_page_addr0` registers in the `status` group.

Copying a Memory Area (Single Plane)

To copy <*PP*> pages from one memory location to another:

1. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the starting address of the area to be copied.
2. Write 0x1000 to the `Data` register.
3. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the starting address of the new area to be written.
4. Write 0x11<*PP*> to the `Data` register, where <*PP*> is the number of pages to copy.

Copying a Memory Area (Multi-Plane)

To copy <*PP*> pages from one memory location to another:

1. Set the flag bit of the multiplane_operation register in the config group to 1.
2. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the starting address of the area to be copied. The address must be plane-aligned.
3. Write 0x1000 to the Data register.
4. Write to the command register, setting the CMD_MAP field to 2 and the BLK_ADDR field to the starting address of the new area to be written. This address must also be plane-aligned.
5. Write 0x11<*PP*> to the Data register, where <*PP*> is the number of pages to copy.

The parameter <*PP*> must be a multiple of the number of planes in the device.

Pipeline Read-Ahead and Write-Ahead Operations

The NAND flash controller supports pipeline read-ahead and write-ahead operations. However, the flash device might have limited support for this function. If the device does not support pipeline read-ahead or write-ahead, the flash controller processes these commands as standard reads or writes.

The NAND flash controller can handle at the most four outstanding pipeline commands, queued up in the order in which the flash controller received the commands. The flash controller operates on the pipeline command at the head of the queue until all the pages corresponding to the pipeline command are executed. The flash controller then pops the pipeline command at the head of the queue and proceeds to work on the next pipeline command in the queue.

The pipeline read-ahead function allows for a continuous reading of the flash memory. On receiving a pipeline read command, the flash controller immediately issues a load command to the device. While data is read out with MAP01 commands in a consecutive or multi-plane address pattern, the flash controller maintains additional cache or multi-plane read command sequencing for continuous streaming of data from the flash device.

The pipeline write-ahead function allows for a continuous writing of the flash memory. While data is written with MAP01 commands in a consecutive or multi-plane address pattern, the NAND flash controller maintains cache or multi-plane command sequences for continuous streaming of data into the flash device.

MAP01 commands must read or write pages in the same sequence that the pipelined commands were issued to the NAND flash controller. If the host issues multiple pipeline commands, pages must be read or written in the order the pipeline commands were issued. It is not possible to read or write pages for a second pipeline command before completing the first pipeline command. If the pipeline sequence is broken by a MAP01 command, the pipe_cmd_err interrupt is issued, and the flash controller clears the pipeline command queue. The flash controller services the violating incoming MAP01 read or write request with a normal page read or write sequence.

For a multi-plane device that supports multi-plane programming, you must set the flag bit of the multiplane_operation register in the config group to 1. In this case, the data is interleaved into page-size chunks to consecutive blocks.

Pipeline read-ahead commands can read data from the queue in this interleaved fashion. The parameter <PP> denotes the total number of pages in multiples of the number of planes available, and the block address must be plane-aligned, which keeps the page address constant while incrementing the block address for each page-size chunk of data. After reading from every plane, the NAND flash controller increments the page address and resets the block address to the initial address. You can also use pipeline write-ahead commands in multi-plane mode. The write operation works similarly to the read operation, holding the page address constant while incrementing the block address until all planes are written.

Note: The same four-entry queue is used to queue the address and page count for pipeline read-ahead and write-ahead commands. This commonality requires that you use MAP01 commands to read out all pages for a pipeline read-ahead command before the next pipeline command can be processed. Similarly, you must write to all pages pertaining to pipeline write-ahead command before the next pipeline command can be processed.

Because the value of the flag bit of the multiplane_operation register in the config group determines pipeline read-ahead or write-ahead behavior, it can only be changed when the pipeline registers are empty.

When the host issues a pipeline read-ahead command, and the flash controller is idle, the load operation occurs immediately.

Note: The read-ahead command does not return the data to the host, and the write-ahead command does not write data to the flash address. The NAND flash controller loads the read data. The read data is returned to the host only when the host issues MAP01 commands to read the data. Similarly, the flash controller loads the write data, and writes it to the flash only when the host issues MAP01 commands to write the data.

A pipe_cpyback_cmd_comp interrupt is generated when the NAND flash controller has finished processing a pipeline command and has discarded that command from its queue. At this point of time, the host can send another pipeline command. A pipeline command is popped from the queue, and an interrupt is issued when the flash controller has started processing the last page of pipeline command. Hence, the pipe_cpyback_cmd_comp interrupt is issued prior to the last page load in the case of a pipeline read command and start of data transfer of the last page to be programmed, in the case of a pipeline write command.

An additional program_comp interrupt is generated when the last page program operation completes in the case of a pipeline write command.

If the device command set requires the NAND flash controller to issue a load command for the last page in the pipeline read command, a load_comp interrupt is generated after the last page load operation completes.

For pipeline write commands, if any page program results in a failure in the device, a program_fail interrupt is issued. The failing page's block and page address is updated in the err_block_addr0 and err_page_addr0 registers in the status group.

The pipeline commands sequence advanced commands in the device, such as cache and multi-plane. When the NAND flash controller receives a multi-page read or write pipeline command, it sequences commands sent to the device depending on settings in the following registers in the config group:

- cache_read_enable
- cache_write_enable
- multiplane_operation

For a device that supports cache read sequences, the flag bit of the cache_read_enable register must be set to 1. The NAND flash controller sequences each multi-page pipeline read command as a cache read sequence. For a device that supports cache program command sequences, cache_write_enable must be set. The flash controller sequences each multi-page write pipeline command as a cache write sequence.

For a device that has multi-planes and supports multi-plane program commands, the NAND flash controller register multiplane_operation, in the config group, must be set. On receiving the multi-page pipeline write command, the flash controller sequences the device with multi-plane program commands and expects that the host transfers data to the flash controller in an even-odd block increment addressing mode.

Set Up a Single Area for Pipeline Read-Ahead

To set up an area for pipeline read-ahead, perform the following steps:

1. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the starting address of the block to pre-read.
2. Write 0x20<*PP*> to the `Data` register, where the 0 sets this command as a read-ahead and <*PP*> is the number of pages to pre-read. The pages must not cross a block boundary. If a block boundary is crossed, the NAND flash controller generates an unsupported command (`unsup_cmd`) interrupt and drops the command.

The read-ahead command is a hint to the flash device to start loading the next page in the page buffer as soon as the previous page buffer operation has completed. After you set up the read-ahead, use a MAP01 command to actually read the data. In the MAP01 command, specify the same starting address as in the read-ahead.

If the read command received following a pipeline read-ahead request is not to a pre-read page, then an interrupt bit is set to 1 and the pipeline read-ahead or write-ahead registers are cleared. You must issue a new pipeline read-ahead request to re-load the same data. You must use MAP01 commands to read all of the data that is pre-read before the NAND flash controller returns to the idle state.

Set Up a Single Area for Pipeline Write-Ahead

To set up an area for pipeline write-ahead:

1. Write to the command register, setting the `CMD_MAP` field to 2 and the `BLK_ADDR` field to the starting address of the block to pre-write.
2. Write 0x21<PP> to the `Data` register, where the value 1 sets this command as a write-ahead and <PP> is the number of pages to pre-write. The pages must not cross a block boundary. If a block boundary is crossed, the NAND flash controller generates an unsupported command (`unsup_cmd`) interrupt and drops the command.

After you set up the write-ahead, use a MAP01 command to actually write the data. In the MAP01 command, specify the same starting address as in the write-ahead.

If the write command received following a pipeline write-ahead request is not to a pre-written page, then an interrupt bit is set to 1 and the pipeline read-ahead or write-ahead registers are cleared. You must issue a new pipeline write-ahead request to configure the write logic.

You must use MAP01 commands to write all of the data that is pre-written before the NAND flash controller returns to the idle state.

NAND Flash Controller Address Map and Register Definitions

The address map and register definitions for the NAND Flash Controller consist of the following regions:

- NAND Flash Controller Module Data
- NAND Flash Controller Module Registers

NAND Controller Module Data (AXI Slave) Address Map on page 13-32
This address space is allocated for indexed addressing by the NAND flash controller. For more information, please refer to the *NAND Flash Controller* chapter of the *Hard Processor System Technical Reference Manual*.

NAND Flash Controller Module Registers (AXI Slave) Address Map on page 13-32
Registers in the NAND Flash Controller module accessible via its register AXI slave

Related Information

Configuration registers Register Descriptions

Common across all types of flash devices, configuration registers setup the basic operating modes of the controller

Offset: 0x0

device_reset on page 13-39
Device reset. Controller sends a RESET command to device. Controller resets bit after sending command to device

transfer_spare_reg on page 13-40
Default data transfer mode. (Ignored during Spare only mode)

load_wait_cnt on page 13-41
Wait count value for Load operation

program_wait_cnt on page 13-41
Wait count value for Program operation

erase_wait_cnt on page 13-42
Wait count value for Erase operation

int_mon_cyccnt on page 13-43
Interrupt monitor cycle count value

rb_pin_enabled on page 13-43
Interrupt or polling mode. Ready/Busy pin is enabled from device.

multiplane_operation on page 13-44
Multiplane transfer mode. Pipelined read, copyback, erase and program commands are transfered in multiplane mode

multiplane_read_enable on page 13-45
Device supports multiplane read command sequence

copyback_disable on page 13-45
Device does not support copyback command sequence

cache_write_enable on page 13-46
Device supports cache write command sequence

cache_read_enable on page 13-46
Device supports cache read command sequence

prefetch_mode on page 13-47
Enables read data prefetching to faster performance

chip_enable_dont_care on page 13-48
Device can work in the chip enable dont care mode

ecc_enable on page 13-48
Enable controller ECC check bit generation and correction

global_int_enable on page 13-49
Global Interrupt enable and Error/Timeout disable.

twhr2_and_we_2_re on page 13-50

tcwaw_and_addr_2_data on page 13-50

re_2_we on page 13-51
Timing parameter between re high to we low (Trhw)

acc_clks on page 13-52
Timing parameter from read enable going low to capture read data

number_of_planes on page 13-52
Number of planes in the device

pages_per_block on page 13-53
Number of pages in a block

device_width on page 13-53
I/O width of attached devices

device_main_area_size on page 13-54
Page main area size of device in bytes

device_spare_area_size on page 13-54
Page spare area size of device in bytes

two_row_addr_cycles on page 13-55
Attached device has only 2 ROW address cycles

multiplane_addr_restrict on page 13-56
Address restriction for multiplane commands

ecc_correction on page 13-56
Correction capability required

read_mode on page 13-57
The type of read sequence that the controller will follow for pipe read commands.

write_mode on page 13-59
The type of write sequence that the controller will follow for pipe write commands.

copyback_mode on page 13-59
The type of copyback sequence that the controller will follow.

rdwr_en_lo_cnt on page 13-60
Read/Write Enable low pulse width

rdwr_en_hi_cnt on page 13-61
Read/Write Enable high pulse width

max_rd_delay on page 13-62
Max round trip read data delay for data capture

cs_setup_cnt on page 13-62
Chip select setup time

spare_area_skip_bytes on page 13-63
Spare area skip bytes

spare_area_marker on page 13-64
Spare area marker value

devices_connected on page 13-64
Number of Devices connected on one bank

die_mask on page 13-65
Indicates the die differentiator in case of NAND devices with stacked dies.

first_block_of_next_plane on page 13-65
The starting block address of the next plane in a multi plane device.

write_protect on page 13-66
This register is used to control the assertion/de-assertion of the WP# pin to the device.

re_2_re on page 13-67
Timing parameter between re high to re low (Trhz) for the next bank

por_reset_count on page 13-67
The number of cycles the controller waits after reset to issue the first RESET command to the device.

watchdog_reset_count on page 13-68
The number of cycles the controller waits before flagging a watchdog timeout interrupt.

device_reset

Device reset. Controller sends a RESET command to device. Controller resets bit after sending command to device

Module Instance	Base Address	Register Address
`nandregs`	`0xFFB80000`	`0xFFB80000`

Offset: 0x0

Access: RW

Bit Fields

device_reset Fields

Bit	Name	Description	Access	Reset
3	bank3	Issues reset to bank 3. Controller resets the bit after reset command is issued to device.	RW	0x0
2	bank2	Issues reset to bank 2. Controller resets the bit after reset command is issued to device.	RW	0x0
1	bank1	Issues reset to bank 1. Controller resets the bit after reset command is issued to device.	RW	0x0
0	bank0	Issues reset to bank 0. Controller resets the bit after reset command is issued to device.	RW	0x0

transfer_spare_reg

Default data transfer mode. (Ignored during Spare only mode)

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80010

Offset: 0x10

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved															flag RW 0x0

transfer_spare_reg Fields

Bit	Name	Description	Access	Reset
0	flag	On all read or write commands through Map 01, if this bit is set, data in spare area of memory will be transfered to host along with main area of data. The main area will be transfered followed by spare area. [list][*]1 - MAIN+SPARE [*]0 - MAIN[/list]	RW	0x0

load_wait_cnt

Wait count value for Load operation

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80020

Offset: 0x20

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x1F4															

load_wait_cnt Fields

Bit	Name	Description	Access	Reset
15:0	value	Number of clock cycles after issue of load operation before NAND Flash Controller polls for status. This values is of relevance for status polling mode of operation and has been provided to minimize redundant polling after issuing a command. After a load command, the first polling will happen after this many number of cycles have elapsed and then on polling will happen every int_mon_cyccnt cycles. The default values is equal to the default value of int_mon_cyccnt	RW	0x1F4

program_wait_cnt

Wait count value for Program operation

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80030

Offset: 0x30

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x1F4															

program_wait_cnt Fields

Bit	Name	Description	Access	Reset
15:0	value	Number of clock cycles after issue of program operation before NAND Flash Controller polls for status. This values is of relevance for status polling mode of operation and has been provided to minimize redundant polling after issuing a command. After a program command, the first polling will happen after this many number of cycles have elapsed and then on polling will happen every int_mon_cyccnt cycles. The default values is equal to the default value of int_mon_cyccnt. The controller internally multiplies the value programmed into this register by 16 to provide a wider range for polling.	RW	0x1F4

erase_wait_cnt

Wait count value for Erase operation

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80040

Offset: 0x40

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved

multiplane_operation Fields

Bit	Name	Description	Access	Reset
0	`flag`	[list][*]1 - Multiplane operation enabled [*]0 - Multiplane operation disabled[/list]	RW	0x0

multiplane_read_enable

Device supports multiplane read command sequence

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80080

Offset: 0x80

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved															flag RW 0x0

multiplane_read_enable Fields

Bit	Name	Description	Access	Reset
0	`flag`	Certain devices support dedicated multiplane read command sequences to read data in the same fashion as is written with multiplane program commands. This bit set should be set for the above devices. When not set, pipeline reads in multiplane mode will still happen in the order of multiplane writes, though normal read command sequences will be issued to the device. [list][*]1 - Device supports multiplane read sequence [*]0 - Device does not support multiplane read sequence[/list]	RW	0x0

copyback_disable

Device does not support copyback command sequence

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80090

Offset: 0x90

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

Reserved															flag RW 0x0

cache_read_enable Fields

Bit	Name	Description	Access	Reset
0	flag	[list][*]1 - Cache read supported [*]0 - Cache read not supported[/list]	RW	0x0

prefetch_mode

Enables read data prefetching to faster performance

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB800C0

Offset: 0xC0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
prefetch_burst_length RW 0x0												Reserved			prefetch_en RW 0x1

prefetch_mode Fields

Bit	Name	Description	Access	Reset
15:4	prefetch_burst_length	If prefetch_en is set and prefetch_burst_length is set to ZERO, the controller will start prefetching data only after the receiving the first Map01 read command for the page. If prefetch_en is set and prefetch_burst_length is set to a non-ZERO, valid value, the controller will start prefetching data corresponding to this value even before the first Map01 for the current page has been received. The value written here should be in bytes.	RW	0x0
0	prefetch_en	Enable prefetch of Data	RW	0x1

chip_enable_dont_care

Device can work in the chip enable dont care mode

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB800D0

Offset: 0xD0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0

chip_enable_dont_care Fields

Bit	Name	Description	Access	Reset
0	flag	Controller can interleave commands between banks when this feature is enabled. [list][*]1 - Device in dont care mode [*]0 - Device cares for chip enable[/list]	RW	0x0

ecc_enable

Enable controller ECC check bit generation and correction

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB800E0

Offset: 0xE0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved															flag RW 0x1

ecc_enable Fields

Bit	Name	Description	Access	Reset
0	flag	Enables or disables controller ECC capabilities. When enabled, controller calculates ECC check-bits and writes them onto device on program operation. On page reads, check-bits are recomputed and errors reported, if any, after comparing with stored check-bits. When disabled, controller does not compute check-bits. [list][*]1 - ECC Enabled [*]0 - ECC disabled[/list]	RW	0x1

global_int_enable

Global Interrupt enable and Error/Timeout disable.

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB800F0

Offset: 0xF0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

re_2_we Fields

Bit	Name	Description	Access	Reset
5:0	value	Signifies the number of bus interface nand_mp_clk clocks that should be introduced between read enable going high to write enable going low. The number of clocks is the function of device parameter Trhw and controller clock frequency.	RW	0x32

acc_clks

Timing parameter from read enable going low to capture read data

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80130

Offset: 0x130

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved												value RW 0x0			

acc_clks Fields

Bit	Name	Description	Access	Reset
3:0	value	Signifies the number of bus interface nand_mp_clk clock cycles, controller should wait from read enable going low to sending out a strobe of nand_mp_clk for capturing of incoming data.	RW	0x0

number_of_planes

Number of planes in the device

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80140

Offset: 0x140

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved													value RW 0x0		

number_of_planes Fields

Bit	Name	Description	Access	Reset
2:0	value	Controller will read Electronic Signature of devices and populate this field as the number of planes information is present in the signature. For 512B device, this information needs to be programmed by software. Software could also choose to override the populated value. The values in the fields should be as follows[list] [*]3'h0 - Monoplane device [*]3'h1 - Two plane device [*]3'h3 - 4 plane device [*]3'h7 - 8 plane device [*]All other values - Reserved[/list]	RW	0x0

pages_per_block

Number of pages in a block

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80150

Offset: 0x150

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x0															

pages_per_block Fields

Bit	Name	Description	Access	Reset
15:0	value	Controller will read Electronic Signature of devices and populate this field. The PAGE512 field of the System Manager NANDGRP_BOOTSTRAP register will determine the value of this field to be of 32. Software could also choose to override the populated value.	RW	0x0

device_width

I/O width of attached devices

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80160

Offset: 0x160

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

Reserved														value RW 0x3	

device_width Fields

Bit	Name	Description	Access	Reset
1:0	value	Controller will read Electronic Signature of devices and populate this field. Software could also choose to override the populated value although only one value is supported. The values in this field should be as follows[list][*]2'h00 - 8bit device[*]All other values - Reserved[/list]	RW	0x3

device_main_area_size

Page main area size of device in bytes

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80170

Offset: 0x170

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x0															

device_main_area_size Fields

Bit	Name	Description	Access	Reset
15:0	value	Controller will read Electronic Signature of devices and populate this field. The PAGE512 field of the System Manager NANDGRP_BOOTSTRAP register will determine the value of this field to be 512. Software could also choose to override the populated value.	RW	0x0

device_spare_area_size

Page spare area size of device in bytes

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80180

Offset: 0x180

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x0															

device_spare_area_size Fields

Bit	Name	Description	Access	Reset
15:0	value	Controller will read Electronic Signature of devices and populate this field. The PAGE512 field of the System Manager NANDGRP_BOOTSTRAP register will determine the value of this field to be 16. Software could also choose to override the populated value.	RW	0x0

two_row_addr_cycles

Attached device has only 2 ROW address cycles

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80190

Offset: 0x190

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved															flag RW 0x0

two_row_addr_cycles Fields

Bit	Name	Description	Access	Reset
0	flag	This flag must be set for devices which allow for 2 ROW address cycles instead of the usual 3. Alternatively, the TWOROWADDR field of the System Manager NANDGRP_BOOTSTRAP register when asserted will set this flag.	RW	0x0

multiplane_addr_restrict

Address restriction for multiplane commands

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB801A0

Offset: 0x1A0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved															flag RW 0x0

multiplane_addr_restrict Fields

Bit	Name	Description	Access	Reset
0	flag	This flag must be set for devices which require that during multiplane operations all but the address for the last plane should have their address cycles tied low. The last plane address cycles has proper values. This ensures multiplane address restrictions in the device.	RW	0x0

ecc_correction

Correction capability required

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB801B0

Offset: 0x1B0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved								value RW 0x8							

ecc_correction Fields

Bit	Name	Description	Access	Reset
7:0	value	The required correction capability can be a number less than the configured error correction capability. A smaller correction capability will lead to lesser number of ECC check-bits being written per ECC sector.	RW	0x8

read_mode

The type of read sequence that the controller will follow for pipe read commands.

Module Instance	Base Address	Register Address

read_mode Fields

Bit	Name	Description	Access	Reset
3:0	value	The values in the field should be as follows[list] [*]4'h0 - This value informs the controller that the pipe read sequence to follow is of a normal read. For 512 byte page devices, Normal read sequence is, C00, Address, Data, ... For devices with page size greater that 512 bytes, the sequence is, C00, Address, C30, Data..... [*]4'h1 - This value informs the controller that the pipe read sequence to follow is of a Cache Read with the following sequence, C00, Address, C30, C31, Data, C31, Data, ..., C3F, Data. [*]4'h2 - This value informs the controller that the pipe read sequence to follow is of a Cache Read with the following sequence, C00, Address, C31, Data, Data, ..., C34. [*]4'h3 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Read with the following sequence, C00, Address, C00, Address, C30, Data, C06, Address, CE0, Data..... [*]4'h4 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Read with the following sequence, C60, Address, C60, Address, C30, C00, Address, C05, Address, CE0, Data, C00, Address, C05, Address, CE0, Data..... [*]4'h5 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Cache Read with the following sequence, C60, Address, C60, Address, C30, C31, C00, Address, C05, Address, CE0, Data, C00, Address, C05, Address, CE0, Data, ..., C3F, C00, Address, C05, Address, CE0, Data, C00, Address, C05, Address, CE0, Data [*]4'h6 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Read with the following sequence, C00, Address, C32, .., C00, Address, C30, C06, Address, CE0, Data, C06, Address, CE0, Data,.... [*]4'h7 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Cache Read with the following sequence, C00, Address, C32,..., C00, Address, C30, C31,C06, Address, CE0, Data, C31, C06, Address, CE0, Data, C3F, C06, Address, CE0, Data.... [*]4'h8 - This value informs the controller that the pipe read sequence to follow is of a 'N' Plane Cache Read with the following sequence, C60, Address, C60, Address, C33, C31, C00, Address, C05, Address, CE0, Data, C00, Address, C05, Address, CE0, Data, ..., C3F, C00, Address, C05, Address, CE0, Data, C00, Address, C05, Address, CE0, Data [*]4'h9 - 4'h15 - Reserved. [/list] ..... indicates that the previous sequence is repeated till the last page.	RW	0x0

write_mode

The type of write sequence that the controller will follow for pipe write commands.

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB801D0

Offset: 0x1D0

Access: RW

Bit Fields

Reserved												value RW 0x0			

copyback_mode Fields

Bit	Name	Description	Access	Reset
3:0	value	The values in the field should be as follows[list] [*]4'h0 - This value informs the controller that the copyback sequence to follow is, C00, Address, C35, C85, Address, C10 [*]4'h1 - This value informs the controller that the copyback sequence to follow is, C00, Address, C30, C8C, Address, C10 [*]4'h2 - This value informs the controller that the copyback sequence to follow is, C00, Address, C8A, Address, C10 [*]4'h3 - This value informs the controller that the copyback sequence to follow is of a four plane copyback sequence, C00, Address, C03, Address, C03, Address, C03, Address, C8A, Address, C11, C8A, Address, C11, C8A, Address, C11, C8A, Address, C10. [*]4'h4 - This value informs the controller that the copyback sequence to follow is of a two plane copyback sequence, C00, Address, C35, C00, Address, C35, C85, Address, C11, C81, Address, C10. [*]4'h5 - This value informs the controller that the copyback sequence to follow is of a two plane copyback sequence, C60, Address, C60, Address, C35, C85, Address, C11, C81, Address, C10. [*]4'h6 - This value informs the controller that the copyback sequence to follow is of a two plane copyback sequence, C00, Address, C00, Address, C35, C85, Address, C11, C80, Address, C10. [*]4'h7 - This value informs the controller that the copyback sequence to follow is of a two plane copyback sequence, C60, Address, C60, Address, C30, C8C, Address, C11, C8C, Address, C10. [*]4'h8 - 4'h15 - Reserved.[/list]	RW	0x0

rdwr_en_lo_cnt

Read/Write Enable low pulse width

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB801F0

Offset: 0x1F0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved											value RW 0x12				

rdwr_en_lo_cnt Fields

Bit	Name	Description	Access	Reset
4:0	value	Number of nand_mp_clk cycles that read or write enable will kept low to meet the min Trp/Twp parameter of the device. The value in this register plus rdwr_en_hi_cnt register value should meet the min cycle time of the device connected. The default value is calculated assuming the max nand_mp_clk time period of 4ns to work with ONFI Mode 0 mode of 100ns device cycle time. This assumes a 1x/4x clocking scheme.	RW	0x12

rdwr_en_hi_cnt

Read/Write Enable high pulse width

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80200

Offset: 0x200

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved											value RW 0xC				

rdwr_en_hi_cnt Fields

Bit	Name	Description	Access	Reset
4:0	value	Number of nand_mp_clk cycles that read or write enable will kept high to meet the min Treh/Tweh parameter of the device. The value in this register plus rdwr_en_lo_cnt register value should meet the min cycle time of the device connected. The default value is calculated assuming the max nand_mp_clk time period of 4ns to work with ONFI Mode 0 mode of 100ns device cycle time. This assumes a 1x/4x clocking scheme.	RW	0xC

max_rd_delay

Max round trip read data delay for data capture

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80210

Offset: 0x210

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved												value RW 0x0			

max_rd_delay Fields

Bit	Name	Description	Access	Reset
3:0	value	Number of nand_mp_clk cycles after generation of feedback nand_mp_clk pulse when it is safe to synchronize received data to nand_mp_clk domain. Data should have been registered with nand_mp_clk and stable by the time max_rd_delay cycles has elapsed. A default value of zero will mean a value of nand_mp_clk multiple minus one.	RW	0x0

cs_setup_cnt

Chip select setup time

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80220

Offset: 0x220

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved											value RW 0x3				

cs_setup_cnt Fields

Bit	Name	Description	Access	Reset
4:0	value	Number of nand_mp_clk cycles required for meeting chip select setup time. This register refers to device timing parameter Tcs. The value in this registers reflects the extra setup cycles for chip select before read/write enable signal is set low. The default value is calculated for ONFI Timing mode 0 Tcs = 70ns and maximum nand_mp_clk period of 4ns for 1x/4x clock multiple for 16ns cycle time device. Please refer to Figure 3.3 for the relationship between the cs_setup_cnt and rdwr_en_lo_cnt values.	RW	0x3

spare_area_skip_bytes

Spare area skip bytes

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80230

Offset: 0x230

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved										value RW 0x0					

spare_area_skip_bytes Fields

Bit	Name	Description	Access	Reset
5:0	value	Number of bytes to skip from start of spare area before last ECC sector data starts. The bytes will be written with the value programmed in the spare_area_marker register. This register could be potentially used to preserve the bad block marker in the spare area by marking it good. The default value is zero which means no bytes will be skipped and last ECC sector will start from the beginning of spare area.	RW	0x0

spare_area_marker

Spare area marker value

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80240

Offset: 0x240

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0xFFFF															

spare_area_marker Fields

Bit	Name	Description	Access	Reset
15:0	value	The value that will be written in the spare area skip bytes. This value will be used by controller while in the MAIN mode of data transfer. Only the least-significant 8 bits of the field value are used.	RW	0xFFFF

devices_connected

Number of Devices connected on one bank

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80250

Offset: 0x250

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved													value RW 0x0		

devices_connected Fields

Bit	Name	Description	Access	Reset
2:0	value	Indicates the number of devices connected to a bank. At reset, the value loaded is the maximum possible devices that could be connected in this configuration.	RW	0x0

die_mask

Indicates the die differentiator in case of NAND devices with stacked dies.

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80260

Offset: 0x260

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved								value RW 0x0							

die_mask Fields

Bit	Name	Description	Access	Reset
7:0	value	The die_mask register information will be used for devices having address restrictions. For example, in certain Samsung devices, when the first address in a two-plane command is being sent, it is expected that the address is all zeros. But if the NAND device internally has multiple dies stacked, the die information (MSB of final row address) has to be sent. The value programmed in this register will be used to mask the address while sending out the last row address.	RW	0x0

first_block_of_next_plane

The starting block address of the next plane in a multi plane device.

Module Instance	Base Address	Register Address
`nandregs`	`0xFFB80000`	`0xFFB80270`

Offset: `0x270`

Access: `RW`

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
`Reserved`															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
`value` `RW 0x1`															

first_block_of_next_plane Fields

Bit	Name	Description	Access	Reset
15:0	`value`	This values informs the controller of the plane structure of the device. In case the device is a multi plane device and the value here is 1, the controller understands that the next plane starts from Block number 1 and in conjunction with the number of planes parameter can decide upon the distribution of blocks in a plane in the device.	`RW`	`0x1`

write_protect

This register is used to control the assertion/de-assertion of the WP# pin to the device.

Module Instance	Base Address	Register Address
`nandregs`	`0xFFB80000`	`0xFFB80280`

Offset: `0x280`

Access: `RW`

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
`Reserved`															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
`Reserved`															`flag` `RW 0x1`

write_protect Fields

Bit	Name	Description	Access	Reset
0	flag	When the controller is in reset, the WP# pin is always asserted to the device. Once the reset is removed, the WP# is de-asserted. The software will then have to come and program this bit to assert/de-assert the same. [list][*]1 - Write protect de-assert [*]0 - Write protect assert[/list]	RW	0x1

re_2_re

Timing parameter between re high to re low (Trhz) for the next bank

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB80290

Offset: 0x290

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved										value RW 0x32					

re_2_re Fields

Bit	Name	Description	Access	Reset
5:0	value	Signifies the number of bus interface nand_mp_clk clocks that should be introduced between read enable going high to a bank to the read enable going low to the next bank. The number of clocks is the function of device parameter Trhz and controller clock frequency.	RW	0x32

por_reset_count

The number of cycles the controller waits after reset to issue the first RESET command to the device.

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB802A0

Offset: 0x2A0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x13B															

por_reset_count Fields

Bit	Name	Description	Access	Reset
15:0	value	The controller waits for this number of cycles before issuing the first RESET command to the device. The number in this register is multiplied internally by 16 in the controller to form the final reset wait count.	RW	0x13B

watchdog_reset_count

The number of cycles the controller waits before flagging a watchdog timeout interrupt.

Module Instance	Base Address	Register Address
nandregs	0xFFB80000	0xFFB802B0

Offset: 0x2B0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
value RW 0x5B9A															

watchdog_reset_count Fields

Bit	Name	Description	Access	Reset
15:0	value	The controller waits for this number of cycles before issuing a watchdog timeout interrupt. The value in this register is multiplied internally by 32 in the controller to form the final watchdog counter.	RW	0x5B9A

Device parameters Register Descriptions

Controller reads device parameters after initialization and stores in the following registers for software

Interrupt and Status Registers Register Descriptions

Contains interrupt and status registers of controller accessible by software.

Offset: 0x400

transfer_mode on page 13-79
Current data transfer mode is Main only, Spare only or Main+Spare. This information is per bank.

intr_status0 on page 13-80
Interrupt status register for bank 0

intr_en0 on page 13-82
Enables corresponding interrupt bit in interrupt register for bank 0

page_cnt0 on page 13-84
Decrementing page count bank 0

err_page_addr0 on page 13-84
Erred page address bank 0

err_block_addr0 on page 13-85
Erred block address bank 0

intr_status1 on page 13-85
Interrupt status register for bank 1

intr_en1 on page 13-87
Enables corresponding interrupt bit in interrupt register for bank 1

page_cnt1 on page 13-88
Decrementing page count bank 1

err_page_addr1 on page 13-89
Erred page address bank 1

err_block_addr1 on page 13-89
Erred block address bank 1

intr_status2 on page 13-90
Interrupt status register for bank 2

intr_en2 on page 13-91
Enables corresponding interrupt bit in interrupt register for bank 2

page_cnt2 on page 13-93
Decrementing page count bank 2

err_page_addr2 on page 13-93
Erred page address bank 2

err_block_addr2 on page 13-94
Erred block address bank 2

intr_status3 on page 13-94
Interrupt status register for bank 3

intr_en3 on page 13-96
Enables corresponding interrupt bit in interrupt register for bank 3

page_cnt3 on page 13-98
Decrementing page count bank 3

err_page_addr3 on page 13-98
Erred page address bank 3

err_block_addr3 on page 13-99
Erred block address bank 3

transfer_mode

Current data transfer mode is Main only, Spare only or Main+Spare. This information is per bank.

Date	Version	Changes
June 2014	2014.06.30	• Added address map and register definitions. • Removed Command DMA section.
February 2014	2014.02.28	Maintenance release
December 2013	2013.12.30	Maintenance release
November 2012	1.2	• Supports one 8-bit device • Show additional supported block sizes • Bad block marker handling
May 2012	1.1	Added programming model section.
January 2012	1.0	Initial release.

SD/MMC Controller 14

2014.06.30

cv_54011 Subscribe Send Feedback

The hard processor system (HPS) provides a Secure Digital/Multimedia Card (SD/MMC) controller for interfacing to external SD and MMC flash cards, secure digital I/O (SDIO) devices, and Consumer Electronics Advanced Transport Architecture (CE-ATA) hard drives. The SD/MMC controller enables you to store boot images and boot the processor system from the removable flash card. You can also use the flash card to expand the on-board storage capacity for larger applications or user data. Other applications include interfacing to embedded SD (eSD) and embedded MMC (eMMC) nonremovable flash devices.

The SD/MMC controller is based on the Synopsys DesignWare Mobile Storage Host (DWC_mobile_storage) controller.

This document refers to SD/SDIO commands, which are documented in detail in the *Physical Layer Simplified Specification, Version 3.01* and the *SDIO Simplified Specification Version 2.00* described on the SD Association website.

Related Information

- **www.sdcard.org**
  To learn more about how SD technology works, visit the SD Association website.
- **Introduction to Cyclone V Hard Processor System** on page 1-1
  The base addresses of all modules are also listed in the Introduction to the Hard Processor System chapter.

Features of the SD/MMC Controller

The HPS SD/MMC controller offers the following features:

- Supports HPS boot from mobile storage
- Supports the following standards or card types:
  - SD, including eSD—version 3.0
  - SDIO, including embedded SDIO (eSDIO)—version 3.0
  - CE-ATA—version 1.1
  - MMC, including eMMC — version 4.41, 1-bit, 4-bit, and 8-bit (in some packages, as described in *MMC Support Matrix*)[(†)]
- Integrated descriptor-based direct memory access (DMA)
- Internal 4 KB receive and transmit FIFO buffer

The SD/MMC controller does not directly support voltage switching, card interrupts, or back-end power control of eSDIO card devices. However, you can connect these signals to general-purpose I/Os (GPIOs).

The SD/MMC controller does not contain a reset output as part of the external card interface. To reset the flash card device, consider using a general purpose output pin.

[33] SDR25 speed mode requires 1.8-V signaling. Note that even if a card supports UHS-I modes (for example SDR50, SDR104, DDR50) it can still communicate at the lower speeds (for example SDR12, SDR25).

[34] Where supported, controls the voltage switch output to support 1.8-V signalling for SD.

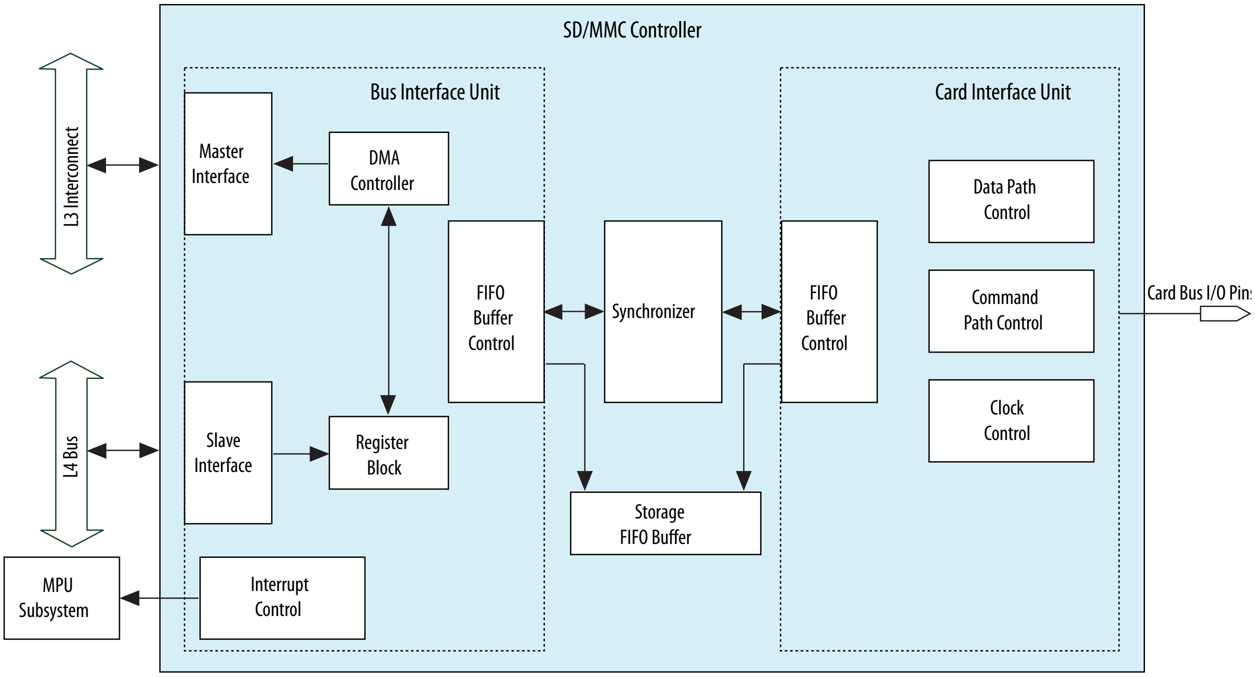
SD/MMC Controller Block Diagram and System Integration

The SD/MMC controller includes a bus interface unit (BIU) and a card interface unit (CIU). The BIU provides a slave interface for a host to access the control and status registers (CSRs). Additionally, this unit also provides independent FIFO buffer access through a DMA interface. The DMA controller is responsible for exchanging data between the system memory and FIFO buffer. The DMA registers are accessible by the host to control the DMA operation. The CIU supports the SD, MMC, and CE-ATA protocols on the controller, and provides clock management through the clock control block. The interrupt control block for generating an interrupt connects to the generic interrupt controller in the ARM Cortex-A9 microprocessor unit (MPU) subsystem.

[35] SPI mode is obsolete in the MMC 4.41 specification.

[36] Supports a maximum clock rate of 50 MHz instead of 52 MHz (specified in MMC specification).

Figure 14-1: SD/MMC Controller Connectivity



Functional Description of the SD/MMC Controller

This section describes the SD/MMC controller components and how the controller operates.

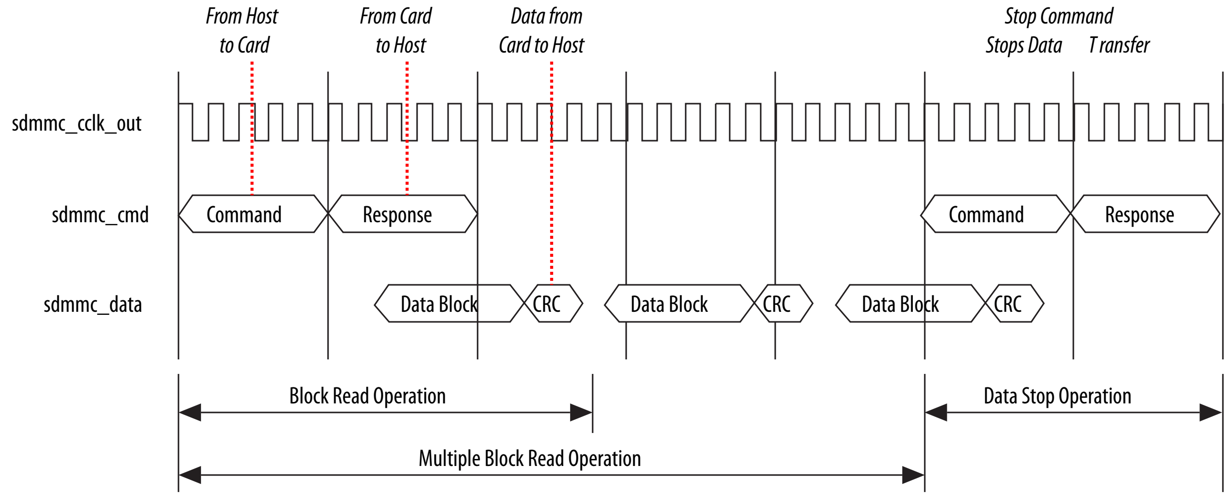
SD/MMC/CE-ATA Protocol

The SD/MMC/CE-ATA protocol is based on command and data bit streams that are initiated by a start bit and terminated by a stop bit. Additionally, the SD/MMC controller provides a reference clock and is the only master interface that can initiate a transaction. †

- Command—a token transmitted serially on the `CMD` pin that starts an operation.†
- Response—a token from the card transmitted serially on the `CMD` pin in response to certain commands.†
- Data—transferred serially using the data pins for data movement commands.†

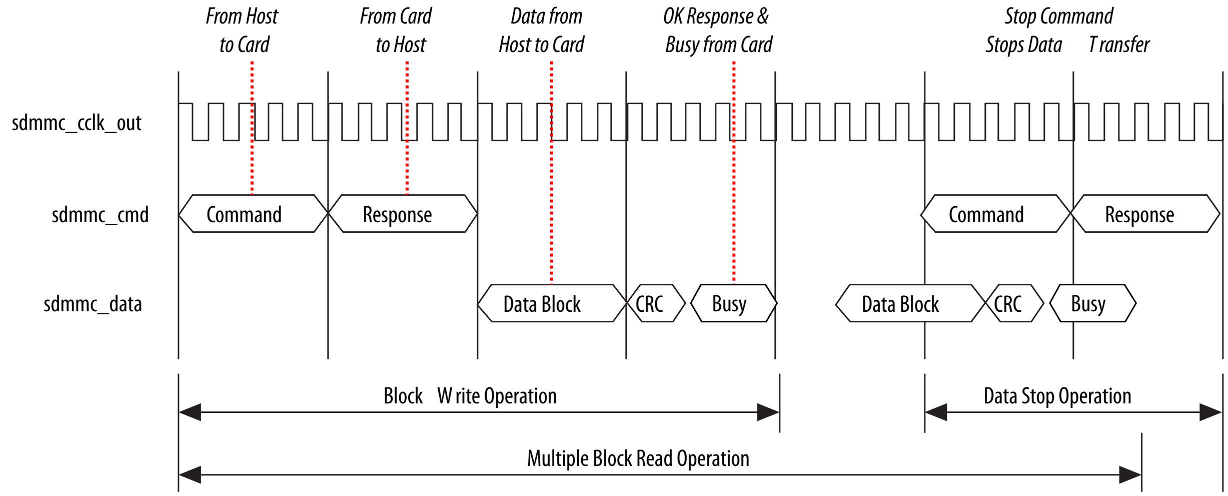
In the following figure, the clock is a representative only and does not show the exact number of clock cycles.†

Figure 14-2: Multiple-Block Read Operation†



The following figure illustrates an example of a command token sent by the host in a multiple-block write operation.

Figure 14-3: Multiple-Block Write Operation†



BIU

The BIU interfaces with the CIU, and is connected to the level 3 (L3) interconnect and level 4 (L4) peripheral buses. The BIU consists of the following primary functional blocks, which are defined in the following sections:

- Slave interface
- Register block
- FIFO buffer
- Interrupt control
- Internal DMA controller

Slave Interface

The host processor accesses the SD/MMC controller registers and data FIFO buffers through the slave interface.

Register Block

The register block is part of the BIU and provides read and write access to the CSRs.†

All registers reside in the BIU clock domain. When a command is sent to a card by setting the start command bit (start_cmd) of the command register (cmd) to 1, all relevant registers needed for the CIU operation are transferred to the CIU block. During this time, software must not write to the registers that are transferred from the BIU to the CIU. The software must wait for the hardware to reset the start_cmd bit to 0 before writing to these registers again. The register unit has a hardware locking feature to prevent illegal writes to registers.†

Registers Locked Out Pending Command Acceptance

After a command start is issued by setting the start_cmd bit of the cmd register, the following registers cannot be rewritten until the command is accepted by the CIU:†

- Command (cmd)†
- Command argument (cmdarg)†
- Byte count (bytcnt)†
- Block size (blksiz)†
- Clock divider (clkdiv)†
- Clock enable (clkena)†
- Clock source (clksrc)†
- Timeout (tmout)†
- Card type (ctype)†

The hardware resets the start_cmd bit after the CIU accepts the command. If a host write to any of these registers is attempted during this locked time, the write is ignored and the hardware lock write error bit (hle) is set to 1 in the raw interrupt status register (rintsts). Additionally, if the interrupt is enabled and not masked for a hardware lock error, an interrupt is sent to the host.†

After a command is accepted, you can send another command to the CIU—which has a one-deep command queue—under the following conditions:†

- If the previous command is not a data transfer command, the new command is sent to the SD/MMC/CE-ATA card once the previous command completes.†
- If the previous command is a data transfer command and if the wait previous data complete bit (wait_prvdata_complete) of the cmd register is set to 1 for the new command, the new command is sent to the SD/MMC/CE-ATA card only when the data transfer completes.†
- If the wait_prvdata_complete bit is 0, the new command is sent to the SD/MMC/CE-ATA card as soon as the previous command is sent. Typically, use this feature to stop or abort a previous data transfer or query the card status in the middle of a data transfer.†

Interrupt Controller Unit

The interrupt controller unit generates an interrupt that depends on the rintsts register, the interrupt mask register (intmask), and the interrupt enable bit (int_enable) of the control register (ctrl). Once an interrupt condition is detected, the controller sets the corresponding interrupt bit in the rintsts register. The bit in the rintsts register remains set to 1 until the software resets the bit to 0 by writing a 1 to the interrupt bit; writing a 0 leaves the bit untouched.

The interrupt port is an active-high, level-sensitive interrupt. The interrupt port is active only when at least one bit in the `rintsts` register is set to 1, the corresponding `intmask` register bit is 1, and the `int_enable` bit of the `ctrl` register is 1.

The following conditions can cause the interrupt to occur:

- SDIO card interrupts
- End-bit error (EBE) on read/No cyclic redundancy code (CRC) on write†
- Auto command done (ACD)†
- Start-bit error (SBE)†
- Hardware locked write error (HLE)†
- FIFO buffer underflow or overflow error (FRUN)†
- Data starvation by host timeout (HTO)†
- Data read timeout (DRTO) or boot data start (BDS)†
- Response timeout (RTO) or boot ACK received (BAR)†
- Data CRC error (DCRC)†
- Response CRC error (RCRC)†
- Receive FIFO buffer data request (RXDR)†
- Transmit FIFO buffer data request (TXDR)†
- Data transfer over (DTO)†
- Command done (CD)†
- Response error (RE)†
- Card-Detect (CDT)†

The `int_enable` bit of the `ctrl` register is set to 0 on power-on, and the `intmask` register bits are set to 0x0000000, which masks all the interrupts.†

Table 14-3: Interrupt Status Register Bits†

Bits	Interrupt	Description
31:16	SDIO Interrupts†	Interrupts from SDIO cards.† One bit for each card. Bit[31] corresponds to Card[15], and bit[16] corresponds to Card[0]. †
15	End Bit Error (read)/Write no CRC (EBE)†	Error in end-bit during read operation, or no data CRC received during write operation.† **Note:** For MMC CMD19, there may be no CRC status returned by the card. Hence, EBE is set for CMD19. The application should not treat this as an error. †

Bits	Interrupt	Description
14	Auto Command Done (ACD)†	Stop/abort commands automatically sent by card unit and not initiated by host; similar to Command Done (CD) interrupt. † **Recommendation:** Software typically need not enable this for non CE-ATA accesses; Data Transfer Over (DTO) interrupt that comes after this interrupt determines whether data transfer has correctly competed. For CE-ATA accesses, if the software sets `send_auto_stop_ccsd` bit in the control register, then software should enable this bit.†
13	Start Bit Error (SBE)†	Error in data start bit when data is read from a card. In 4-bit mode, if all data bits do not have start bit, then this error is set. †
12	Hardware Locked write Error (HLE)†	During hardware-lock period, write attempted to one of locked registers. †
11	FIFO Underrun/Overrun Error (FRUN)†	Host tried to push data when FIFO was full, or host tried to read data when FIFO was empty. Typically this should not happen, except due to error in software. † Card unit never pushes data into FIFO when FIFO is full, and pop data when FIFO is empty. † If IDMAC (Internal Direct Memory Access Controller) is enabled, FIFO underrun/overrun can occur due to a programming error on MSIZE and watermark values in FIFOTH register; for more information, refer to *Internal Direct Memory Access Controller (IDMAC)* section in the "Synopsys DesignWare Cores Mobile Storage Host Databook".†

Bits	Interrupt	Description
10	Data Starvation by Host Timeout (HTO)[†]	To avoid data loss, card clock out (`cclk_out`) is stopped if FIFO is empty when writing to card, or FIFO is full when reading from card. Whenever card clock is stopped to avoid data loss, data-starvation timeout counter is started with data-timeout value. This interrupt is set if host does not fill data into FIFO during write to card, or does not read from FIFO during read from card before timeout period. [†] Even after timeout, card clock stays in stopped state, with CIU state machines waiting. It is responsibility of host to push or pop data into FIFO upon interrupt, which automatically restarts `cclk_out` and card state machines. [†] Even if host wants to send stop/abort command, it still must ensure to push or pop FIFO so that clock starts in order for stop/abort command to send on cmd signal along with data that is sent or received on data line. [†]
9	Data Read Timeout (DRTO)/Boot Data Start (BDS)[†]	• In Normal functioning mode: Data read timeout (DRTO) Data timeout occurred. Data Transfer Over (DTO) also set if data timeout occurs. [†] • In Boot Mode: Boot Data Start (BDS) When set, indicates that DWC_mobile_storage has started to receive boot data from the card. A write to this register with a value of 1 clears this interrupt.[†]
8	Response Timeout (RTO)/ Boot Ack Received (BAR)[†]	• In Normal functioning mode: Response timeout (RTO) Response timeout occurred. Command Done (CD) also set if response timeout occurs. If command involves data transfer and when response times out, no data transfer is attempted by DWC_mobile_storage.[†] • In Boot Mode: Boot Ack Received (BAR) When expect_boot_ack is set, on reception of a boot acknowledge pattern—0-1-0—this interrupt is asserted. A write to this register with a value of 1 clears this interrupt.[†]
7	Data CRC Error (DCRC)[†]	Received Data CRC does not match with locally-generated CRC in CIU; expected when a negative CRC is received. [†]

Bits	Interrupt	Description
6	Response CRC Error (RCRC)†	Response CRC does not match with locally-generated CRC in CIU.†
5	Receive FIFO Data Request (RXDR)†	Interrupt set during read operation from card when FIFO level is greater than Receive-Threshold level.† **Recommendation:** In DMA modes, this interrupt should not be enabled.† ISR, in non-DMA mode: `pop RX_WMark + 1 data from FIFO` †

4	Transmit FIFO Data Request (TXDR)†	Interrupt set during write operation to card when FIFO level reaches less than or equal to Transmit-Threshold level.†
		Recommendation: In DMA modes, this interrupt should not be enabled.†
		ISR in non-DMA mode: †
		`if (pending_bytes > \†`
		`(FIFO_DEPTH - TX_WMark))†`
		`     push (FIFO_DEPTH - \†`
		`     TX_WMark) data into FIFO†`
		`else†`
		`     push pending_bytes data \†`
		`     into FIFO†`

3	Data Transfer (DTO)†	Data transfer completed, even if there is Start Bit Error or CRC error. This bit is also set when “read data-timeout” occurs or CCS is sampled from CE-ATA device.† **Recommendation:** In non-DMA mode, when data is read from card, on seeing interrupt, host should read any pending data from FIFO. In DMA mode, DMA controllers guarantee FIFO is flushed before interrupt.† **Note:** DTO bit is set at the end of the last data block, even if the device asserts MMC busy after the last data block.†
2	Command Done (CD)†	Command sent to card and received response from card, even if Response Error or CRC error occurs. Also set when response timeout occurs or CCSD sent to CE-ATA device.†

Bits	Interrupt	Description
1	Response Error (RE)†	Error in received response set if one of following occurs:† • Transmission bit != 0† • Command index mismatch† • End-bit != 1†
0	Card-Detect (CDT)†	When one or more cards inserted or removed, this interrupt occurs. Software should read card-detect register (CDETECT, 0x50) to determine current card status.† **Recommendation:** After power-on and before enabling interrupts, software should read card detect register and store it in memory. When interrupt occurs, it should read card detect register and compare it with value stored in memory to determine which card(s) were removed/inserted. Before exiting ISR, software should update memory with new card-detect value.†

Interrupt Setting and Clearing

The SDIO Interrupts, Receive FIFO Data Request, and Transmit FIFO Data Request interrupts are set by level-sensitive interrupt sources. Therefore, the interrupt source must be first cleared before you can reset the interrupt's corresponding bit in the `rintsts` register to 0.†

For example, on receiving the Receive FIFO Data Request interrupt, the FIFO buffer must be emptied so that the FIFO buffer count is not greater than the RX watermark, which causes the interrupt to be triggered.†

The rest of the interrupts are triggered by single clock-pulse-width sources.†

FIFO Buffer

The SD/MMC controller has a 4 KB data FIFO buffer for storing transmit and receive data. The FIFO buffer memory supports error correction codes (ECCs). Both interfaces to the FIFO buffer support single and double bit error injection. The enable and error injection pins are inputs driven by the system manager and the status pins are outputs driven to the MPU subsystem.

The SD/MMC controller provides outputs to notify the system manager when single-bit correctable errors are detected (and corrected), and when double-bit (uncorrectable) errors are detected. The system manager generates an interrupt to the GIC when an ECC error is detected.

Related Information

System Manager on page 5-1

Internal DMA Controller

The internal DMA controller has a CSR and a single transmit or receive engine, which transfers data from system memory to the card and vice versa. The controller uses a descriptor mechanism to efficiently move data from source to destination with minimal host processor intervention. You can set up the controller to interrupt the host processor in situations such as transmit and receive data transfer completion from the card, as well as other normal or error conditions. The DMA controller and the host driver communicate through a single data structure.†

The internal DMA controller transfers the data received from the card to the data buffer in the system memory, and transfers transmit data from the data buffer in the memory to the controller's FIFO buffer. Descriptors that reside in the system memory act as pointers to these buffers.†

A data buffer resides in the physical memory space of the system memory and consists of complete or partial data. The buffer status is maintained in the descriptor. Data chaining refers to data that spans multiple data buffers. However, a single descriptor cannot span multiple data buffers.†

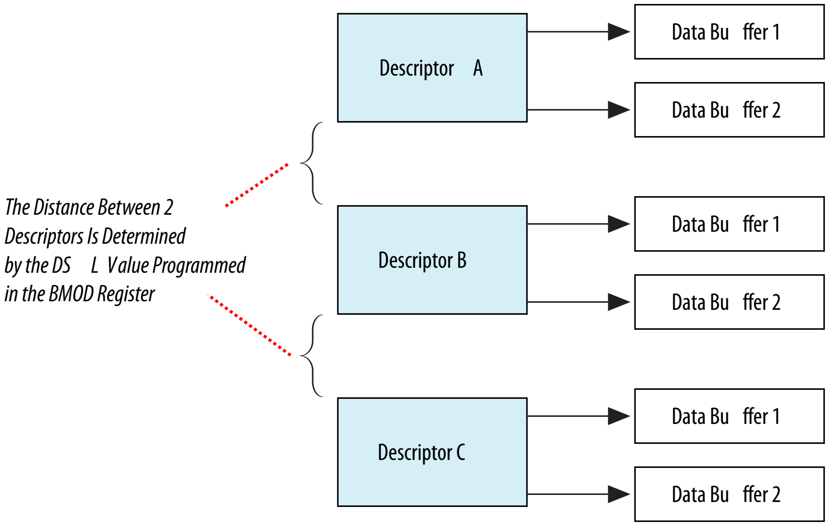
A single descriptor is used for both reception and transmission. The base address of the list is written into the descriptor list base address register (`dbaddr`). A descriptor list is forward linked. The last descriptor can point back to the first entry to create a ring structure. The descriptor list resides in the physical memory address space of the host. Each descriptor can point to a maximum of two data buffers.†

Internal DMA Controller Descriptors

The internal DMA controller uses these types of descriptor structures:†

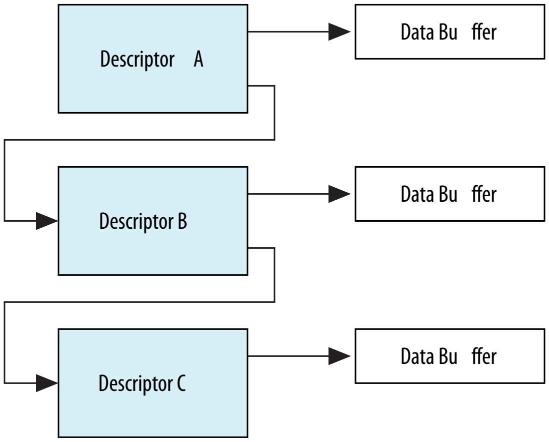
- Dual-buffer structure—The distance between two descriptors is determined by the skip length value written to the descriptor skip length field (`dsl`) of the bus mode register (`bmod`).†

Figure 14-4: Dual-Buffer Descriptor Structure†



- Chain structure—Each descriptor points to a unique buffer, and to the next descriptor in a linked list.†

Figure 14-5: Chain Descriptor Structure†



Internal DMA Controller Descriptor Address

The descriptor address must be aligned to the 32-bit bus. Each descriptor contains 16 bytes of control and status information.†

Table 14-4: Descriptor Format

Name	Offset	31	30	29 ...	26	25 ...	13	12 ...	6	5	4	3	2	1	0
DES 0	0	OWN	CES	—						ER	CH	FS	LD	DIC	—
DES 1	4	—				BS2			BS1						
DES 2	8	BAP1													
DES 3	12	BAP2 or Next Descriptor Address													

Related Information

Internal DMA Controller Descriptor Fields on page 14-13
Refer to this table for information about each of the bits of the descriptor.

Internal DMA Controller Descriptor Fields

The DES0 field in the internal DMA controller descriptor contains control and status information.

Table 14-5: Internal DMA Controller DES0 Descriptor Field†

Bits	Name	Description
31	OWN	When set to 1, this bit indicates that the descriptor is owned by the internal DMA controller. When this bit is set to 0, it indicates that the descriptor is owned by the host. The internal DMA controller resets this bit to 0 when it completes the data transfer.
30	Card Error Summary (CES)	The CES bit indicates whether a transaction error occurred. The CES bit is the logical OR of the following error bits in the `rintsts` register. • End-bit error (`ebe`) • Response timeout (`rto`) • Response CRC (`rcrc`) • Start-bit error (`sbe`) • Data read timeout (`drto`) • Data CRC for receive (`dcrc`) • Response error (`re`)
29:6	Reserved	—
5	End of Ring (ER)	When set to 1, this bit indicates that the descriptor list reached its final descriptor. The internal DMA controller returns to the base address of the list, creating a descriptor ring. ER is meaningful for only a dual-buffer descriptor structure.
4	Second Address Chained (CH)	When set to 1, this bit indicates that the second address in the descriptor is the next descriptor address rather than the second buffer address. When this bit is set to 1, BS2 (DES1[25:13]) must be all zeros.
3	First Descriptor (FS)	When set to 1, this bit indicates that this descriptor contains the first buffer of the data. If the size of the first buffer is 0, next descriptor contains the beginning of the data.
2	Last Descriptor (LD)	When set to 1, this bit indicates that the buffers pointed to by this descriptor are the last buffers of the data.
1	Disable Interrupt on Completion (DIC)	When set to 1, this bit prevents the setting of the TI/RI bit of the internal DMA controller status register (`idsts`) for the data that ends in the buffer pointed to by this descriptor.
0	Reserved	—

The DES1 descriptor field contains the buffer size.

Table 14-6: Internal DMA Controller DES1 Descriptor Field†

Bits	Name	Description
31:26	Reserved	—
25:13	Buffer 2 Size (BS2)	These bits indicate the second data buffer byte size. The buffer size must be a multiple of four. When the buffer size is not a multiple of four, the resulting behavior is undefined. This field is not valid if DES0[4] is set to 1.
12:0	Buffer 1 Size (BS1)	Indicates the data buffer byte size, which must be a multiple of four bytes. When the buffer size is not a multiple of four, the resulting behavior is undefined. If this field is 0, the DMA ignores the buffer and proceeds to the next descriptor for a chain structure, or to the next buffer for a dual-buffer structure. If there is only one descriptor and only one buffer to be programmed, you need to use only buffer 1 and not buffer 2.

The DES2 descriptor field contains the address pointer to the data buffer.

Table 14-7: Internal DMA Controller DES2 Descriptor Field†

Bits	Name	Description
31:0	Buffer Address Pointer 1 (BAP1)	These bits indicate the physical address of the first data buffer. The internal DMA controller ignores DES2 [1:0], because it only performs 32-bit aligned accesses.

The DES3 descriptor field contains the address pointer to the next descriptor if the present descriptor is not the last descriptor in a chained descriptor structure or the second buffer address for a dual-buffer structure.†

Table 14-8: Internal DMA Controller DES3 Descriptor Field†

Bits	Name	Description
31:0	Buffer Address Pointer 2 (BAP2) or Next Descriptor Address	These bits indicate the physical address of the second buffer when the dual-buffer structure is used. If the Second Address Chained (DES0[4]) bit is set to 1, this address contains the pointer to the physical memory where the next descriptor is present. If this is not the last descriptor, the next descriptor address pointer must be aligned to 32 bits. Bits 1 and 0 are ignored.

Host Bus Burst Access

The internal DMA controller attempts to issue fixed-length burst transfers on the master interface if configured using the fixed burst bit (fb) of the bmod register. The maximum burst length is indicated and limited by the programmable burst length (pbl) field of the bmod register. When descriptors are being fetched, the master interface always presents a burst size of four to the interconnect.†

The internal DMA controller initiates a data transfer only when sufficient space to accommodate the configured burst is available in the FIFO buffer or the number of bytes to the end of transfer is less than the configured burst-length. When the DMA master interface is configured for fixed-length bursts, it transfers data using the most efficient combination of INCR4/8/16 and SINGLE transactions. If the DMA master interface is not configured for fixed length bursts, it transfers data using INCR (undefined length) and SINGLE transactions.†

Host Data Buffer Alignment

The transmit and receive data buffers in system memory must be aligned to a 32-bit boundary.

Buffer Size Calculations

The driver knows the amount of data to transmit or receive. For transmitting to the card, the internal DMA controller transfers the exact number of bytes from the FIFO buffer, indicated by the buffer size field of the DES1 descriptor field.†

If a descriptor is not marked as last (with the LD bit of the DES0 field set to 0) then the corresponding buffer(s) of the descriptor are considered full, and the amount of valid data in a buffer is accurately indicated by its buffer size field. If a descriptor is marked as last, the buffer might or might not be full, as indicated by the buffer size in the DES1 field. The driver is aware of the number of locations that are valid.† The driver is expected to ignore the remaining, invalid bytes.

Internal DMA Controller Interrupts

Interrupts can be generated as a result of various events. The idsts register contains all the bits that might cause an interrupt. The internal DMA controller interrupt enable register (idinten) contains an enable bit for each of the events that can cause an interrupt to occur.†

There are two summary interrupts—the normal interrupt summary bit (nis) and the abnormal interrupt summary bit (ais)—in the idsts register.† The nis bit results from a logical OR of the transmit interrupt (ti) and receive interrupt (ri) bits in the idsts register. The ais bit is a logical OR result of the fatal bus error interrupt (fbe), descriptor unavailable interrupt (du), and card error summary interrupt (ces) bits in the idsts register.

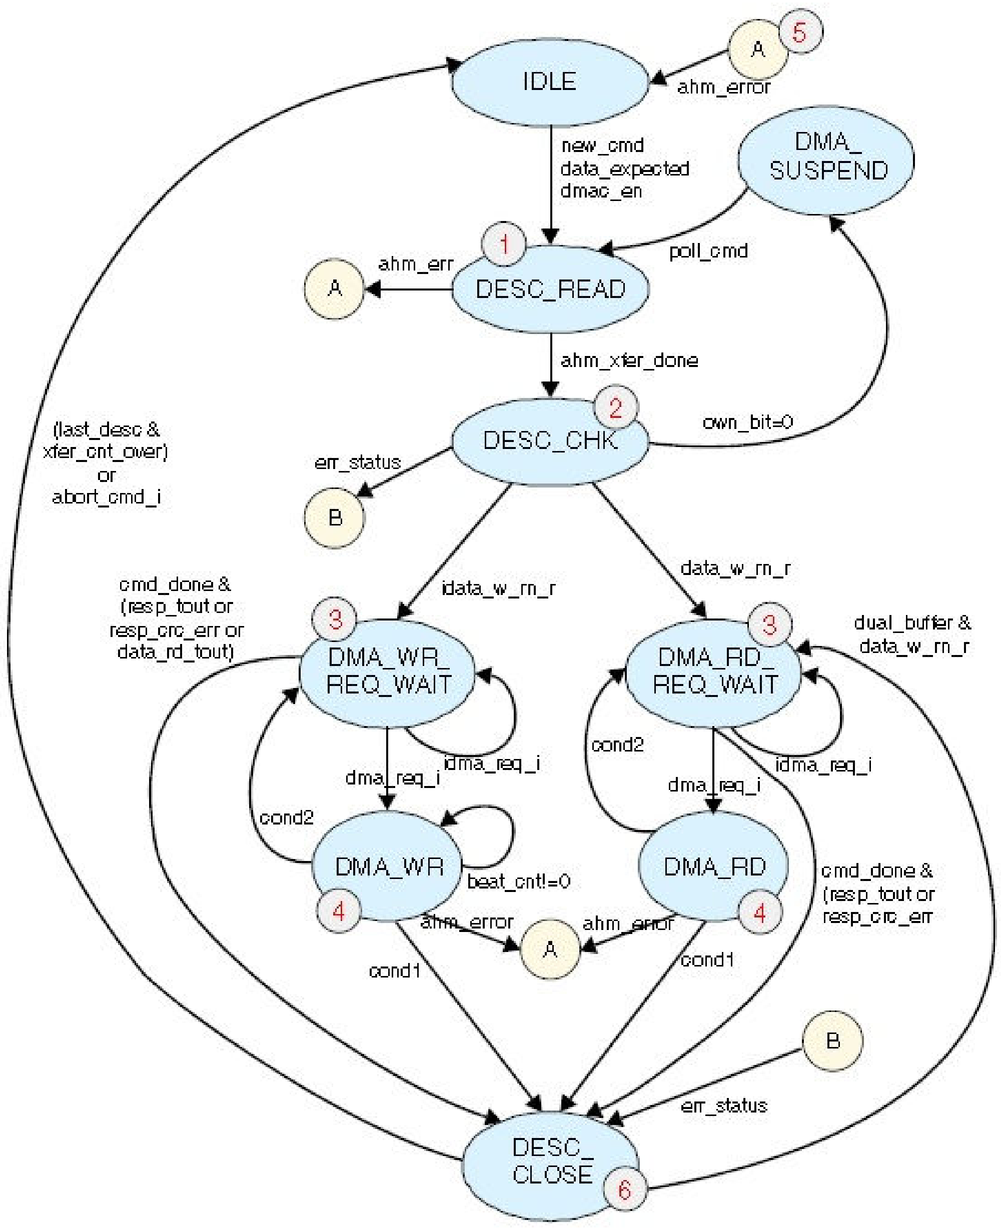
Interrupts are cleared by writing a 1 to the corresponding bit position.† If a 0 is written to an interrupt's bit position, the write is ignored, and does not clear the interrupt. When all the enabled interrupts within a group are cleared, the corresponding summary bit is set to 0. When both the summary bits are set to 0, the interrupt signal is de-asserted.†

Interrupts are not queued. If another interrupt event occurs before the driver has responded to the previous interrupt, no additional interrupts are generated. For example, the ri bit of the idsts register indicates that one or more data has been transferred to the host buffer.†

An interrupt is generated only once for simultaneous, multiple events. The driver must scan the idsts register for the interrupt cause.† The final interrupt signal from the controller is a logical OR of the interrupts from the BIU and internal DMA controller.

Internal DMA Controller FSM

Figure 14-6: Internal DMA Controller Functional State Machine[†]



The following list explains each state of the functional state machine:[†]

1. The internal DMA controller performs four accesses to fetch a descriptor.[†]
2. The DMA controller stores the descriptor information internally. If it is the first descriptor, the controller issues a FIFO buffer reset and waits until the reset is complete.[†]
3. The internal DMA controller checks each bit of the descriptor for the correctness. If bit mismatches are found, the appropriate error bit is set to 1 and the descriptor is closed by setting the OWN bit in the DES0 field to 1.[†]

   The `rintsts` register indicates one of the following conditions:[†]

- Response timeout†
- Response CRC error†
- Data receive timeout†
- Response error†

4. The DMA waits for the RX watermark to be reached before writing data to system memory, or the TX watermark to be reached before reading data from system memory. The RX watermark represents the number of bytes to be locally stored in the FIFO buffer before the DMA writes to memory. The TX watermark represents the number of free bytes in the local FIFO buffer before the DMA reads data from memory.†
5. If the value of the programmable burst length (PBL) field is larger than the remaining amount of data in the buffer, single transfers are initiated. If dual buffers are being used, and the second buffer contains no data (buffer size = 0), the buffer is skipped and the descriptor is closed.†
6. The OWN bit in descriptor is set to 0 by the internal DMA controller after the data transfer for one descriptor is completed. If the transfer spans more than one descriptor, the DMA controller fetches the next descriptor. If the transfer ends with the current descriptor, the internal DMA controller goes to idle state after setting the `ri` bit or the `ti` bit of the `idsts` register. Depending on the descriptor structure (dual buffer or chained), the appropriate starting address of descriptor is loaded. If it is the second data buffer of dual buffer descriptor, the descriptor is not fetched again.†

Abort During Internal DMA Transfer

If the host issues an SD/SDIO STOP_TRANSMISSION command (CMD12) to the card while data transfer is in progress, the internal DMA controller closes the present descriptor after completing the data transfer until a Data Transfer Over (DTO) interrupt is asserted. Once a STOP_TRANSMISSION command is issued, the DMA controller performs single burst transfers.†

- For a card write operation, the internal DMA controller keeps writing data to the FIFO buffer after fetching it from the system memory until a DTO interrupt is asserted. This is done to keep the card clock running so that the STOP_TRANSMISSION command is reliably sent to the card.†
- For a card read operation, the internal DMA controller keeps reading data from the FIFO buffer and writes to the system memory until a DTO interrupt is generated. This is required because DTO interrupt is not generated until and unless all the FIFO buffer data is emptied.†

Note: For a card write abort, only the current descriptor during which a STOP_TRANSMISSION command is issued is closed by the internal DMA controller. The remaining unread descriptors are not closed by the internal DMA controller.†

Note: For a card read abort, the internal DMA controller reads the data out of the FIFO buffer and writes them to the corresponding descriptor data buffers. The remaining unread descriptors are not closed.†

Fatal Bus Error Scenarios

A fatal bus error occurs due to an error response through the master interface. This error is a system error, so the software driver must not perform any further setup on the controller. The only recovery mechanism from such scenarios is to perform one of the following tasks:†

- Issue a reset to the controller through the reset manager.†
- Issue a program controller reset by writing to the controller reset bit (`controller_reset`) of the `ctrl` register.†

FIFO Buffer Overflow and Underflow

During normal data transfer conditions, FIFO buffer overflow and underflow does not occur. However, if there is a programming error, a FIFO buffer overflow or underflow can result. For example, consider the following scenarios.†

For transmit:†

- PBL=4†
- TX watermark = 1†

For these programming values, if the FIFO buffer has only one location empty, the DMA attempts to read four words from memory even though there is only one word of storage available. This results in a FIFO Buffer Overflow interrupt.†

For receive:†

- PBL=4†
- RX watermark = 1†

For these programming values, if the FIFO buffer has only one location filled, the DMA attempts to write four words, even though only one word is available. This results in a FIFO Buffer Underflow interrupt.†

The driver must ensure that the number of bytes to be transferred, as indicated in the descriptor, is a multiple of four bytes. For example, if the `bytcnt` register = 13, the number of bytes indicated in the descriptor must be rounded up to 16 because the length field must always be a multiple of four bytes.†

PBL and Watermark Levels

This table shows legal PBL and FIFO buffer watermark values for internal DMA controller data transfer operations.†

Table 14-9: PBL and Watermark Levels†

PBL (Number of transfers)	TX/RX FIFO Buffer Watermark Value
1	greater than or equal to 1
4	greater than or equal to 4
8	greater than or equal to 8
16	greater than or equal to 16
32	greater than or equal to 32
64	greater than or equal to 64
128	greater than or equal to 128
256	greater than or equal to 256

CIU

The CIU interfaces with the BIU and SD/MMC cards or devices. The host processor writes command parameters to the SD/MMC controller's BIU control registers and these parameters are then passed to the CIU. Depending on control register values, the CIU generates SD/MMC command and data traffic on the card bus according to the SD/MMC protocol. The control register values also decide whether the command and data traffic is directed to the CE-ATA card, and the SD/MMC controller controls the command and data path accordingly.†

The following list describes the CIU operation restrictions:†

- After a command is issued, the CIU accepts another command only to check read status or to stop the transfer.†
- Only one data transfer command can be issued at a time.†
- During an open-ended card write operation, if the card clock is stopped because the FIFO buffer is empty, the software must first fill the data into the FIFO buffer and start the card clock. It can then issue only an SD/SDIO STOP_TRANSMISSION (CMD12) command to the card.†
- During an SDIO/COMBO card transfer, if the card function is suspended and the software wants to resume the suspended transfer, it must first reset the FIFO buffer and start the resume command as if it were a new data transfer command.†
- When issuing SD/SDIO card reset commands (GO_IDLE_STATE, GO_INACTIVE_STATE or CMD52_reset) while a card data transfer is in progress, the software must set the stop abort command bit (`stop_abort_cmd`) in the `cmd` register to 1 so that the controller can stop the data transfer after issuing the card reset command.†
- If the card clock is stopped because the FIFO buffer is full during a card read, the software must read at least two FIFO buffer locations to start the card clock.†
- If CE-ATA card device interrupts are enabled (the `nIEN` bit is set to 0 in the ATA control register), a new RW_BLK command must not be sent to the same card device if there is a pending RW_BLK command in progress (the RW_BLK command used in this document is the RW_MULTIPLE_BLOCK MMC command defined by the CE-ATA specification). Only the Command Completion Signal Disable (CCSD) command can be sent while waiting for the Command Completion Signal (CCS).†
- For the same card device, a new command is allowed for reading status information, if interrupts are disabled in the CE-ATA card (the `nIEN` bit is set to 1 in the ATA control register).†
- Open-ended transfers are not supported for the CE-ATA card devices.†
- The `send_auto_stop` signal is not supported (software must not set the `send_auto_stop` bit in the `cmd` register) for CE-ATA transfers.†

The CIU consists of the following primary functional blocks:†

- Command path†
- Data path†
- Clock control†

Command Path

The command path performs the following functions:†

- Load card command parameters†
- Send commands to card bus†
- Receive responses from card bus†
- Send responses to BIU†
- Load clock parameters†
- Drives the P-bit on command pin†

A new command is issued to the controller by writing to the BIU registers and setting the `start_cmd` bit in the `cmd` register. The command path loads the new command (command, command argument, timeout) and sends an acknowledgement to the BIU.†

After the new command is loaded, the command path state machine sends a command to the card bus—including the internally generated seven-term CRC (CRC-7)—and receives a response, if any. The state machine then sends the received response and signals to the BIU that the command is done, and then waits for eight clock cycles before loading a new command. In CE-ATA data payload transfer (RW_MULTIPLE_BLOCK) commands, if the card device interrupts are enabled (the nIEN bit is set to 0 in the ATA control register), the state machine performs the following actions after receiving the response:†

- Does not drive the P-bit; it waits for CCS, decodes and goes back to idle state, and then drives the P-bit.†
- If the host wants to send the CCSD command and if eight clock cycles are expired after the response, it sends the CCSD pattern on the command pin.†

Load Command Parameters

Commands or responses are loaded in the command path in the following situations:†

- New command from BIU—When the BIU sends a new command to the CIU, the `start_cmd` bit is set to 1 in the `cmd` register.†
- Internally-generated `send_auto_stop`—When the data path ends, the SD/SDIO STOP command request is loaded.†
- Interrupt request (IRQ) response with relative card address (RCA) 0x000—When the command path is waiting for an IRQ response from the MMC and a “send irq response” request is signaled by the BIU, the send IRQ request bit (`send_irq_response`) is set to 1 in the `ctrl` register.†

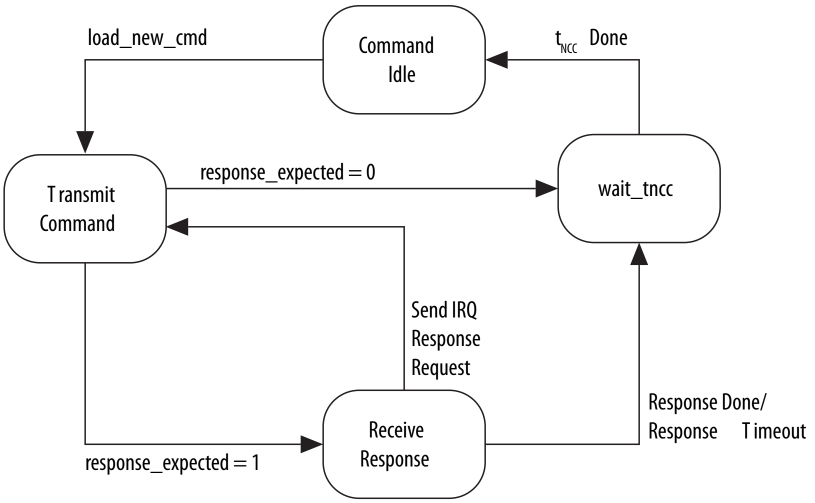
Loading a new command from the BIU in the command path depends on the following `cmd` register bit settings:†

- `update_clock_registers_only`—If this bit is set to 1 in the `cmd` register, the command path updates only the `clkena`, `clkdiv`, and `clksrc` registers. If this bit is set to 0, the command path loads the `cmd`, `cmdarg`, and `tmout` registers. It then processes the new command, which is sent to the card.†
- `wait_prvdata_complete`—If this bit is set to 1, the command path loads the new command under one of the following conditions:†
  - Immediately, if the data path is free (that is, there is no data transfer in progress), or if an open-ended data transfer is in progress (`bytcnt` = 0).†
  - After completion of the current data transfer, if a predefined data transfer is in progress.†

Send Command and Receive Response

After a new command is loaded in the command path (the `update_clock_registers_only` bit in the `cmd` register is set to 0), the command path state machine sends out a command on the card bus.†

Figure 14-7: Command Path State Machine†



The command path state machine performs the following functions, according to cmd register bit values:[†]

1. send_initialization—Initialization sequence of 80 clock cycles is sent before sending the command.[†]
2. response_expected—A response is expected for the command. After the command is sent out, the command path state machine receives a 48-bit or 136-bit response and sends it to the BIU. If the start bit of the card response is not received within the number of clock cycles (as set up in the tmout register), the rto bit and command done (CD) bit are set to 1 in the rintsts register, to signal to the BIU. If the response-expected bit is set to 0, the command path sends out a command and signals a response done to the BIU, which causes the cmd bit to be set to 1 in the rintsts register.[†]
3. response_length—If this bit is set to 1, a 136-bit long response is received; if it is set to 0, a 48-bit short response is received.[†]
4. check_response_crc—If this bit is set to 1, the command path compares CRC-7 received in the response with the internally-generated CRC-7. If the two do not match, the response CRC error is signaled to the BIU, that is, the rcrc bit is set to 1 in the rintsts register.[†]

Send Response to BIU

If the response_expected bit is set to 1 in the cmd register, the received response is sent to the BIU. Response register 0 (resp0) is updated for a short response, and the response register 3 (resp3), response register 2 (resp2), response register 1 (resp1), and resp0 registers are updated on a long response, after which the cmd bit is set to 1 in the rintsts register. If the response is for an AUTO_STOP command sent by the CIU, the response is written to the resp1 register, after which the auto command done bit (acd) is set to 1 in the rintsts register.[†]

The command path verifies the contents of the card response.

Table 14-10: Card Response Fields[†]

Field	Contents
Response transmission bit	0
Command index	Command index of the sent command
End bit	1

The command index is not checked for a 136-bit response or if the check_response_crc bit in the cmd register is set to 0. For a 136-bit response and reserved CRC 48-bit responses, the command index is reserved, that is, 0b111111.[†]

www.sdcard.org

For more information about response values, refer to Physical Layer Simplified Specification, Version 3.01 as described on the SD Association website.

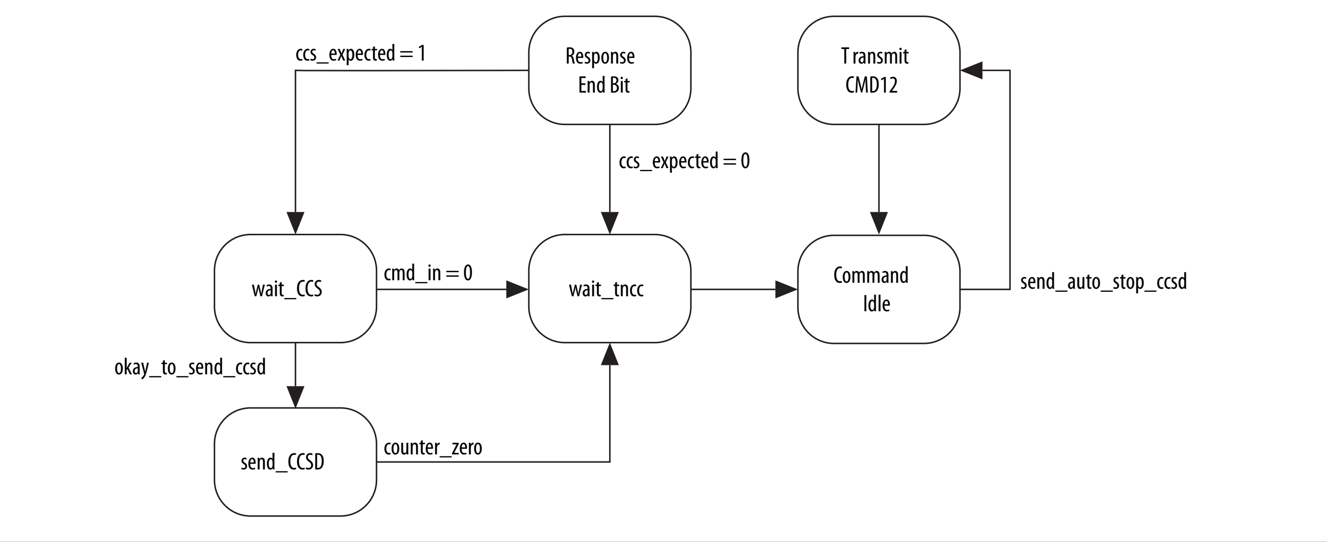
Driving P-bit to the CMD Pin

The command path drives a one-cycle pull-up bit (P-bit) to 1 on the CMD pin between two commands if a response is not expected. If a response is expected, the P-bit is driven after the response is received and before the start of the next command. While accessing a CE-ATA card device, for commands that expect a CCS, the P-bit is driven after the response only if the interrupts are disabled in the CE-ATA card (the nIEN bit is set to 1 in the ATA control register), that is, the CCS expected bit (ccs_expected) in the cmd register is set to 0. If the command expects the CCS, the P-bit is driven only after receiving the CCS.[†]

Polling the CCS

CE-ATA card devices generate the CCS to notify the host controller of the normal ATA command completion or ATA command termination. After receiving the response from the card, the command path state machine performs the functions illustrated in the following figure according to `cmd` register bit values.†

Figure 14-8: CE-ATA Command Path State Machine†



The above figure illustrates:

- Response end bit state—The state machine receives the end bit of the response from the card device. If the `ccs_expected` bit of the `cmd` register is set to 1, the state machine enters the wait CCS state.†
- Wait CCS—The state machine waits for the CCS from the CE-ATA card device. While waiting for the CCS, the following events can happen:†

  1. Software sets the send CCSD bit (`send_ccsd`) in the `ctrl` register, indicating not to wait for CCS and to send the CCSD pattern on the command line.†
  2. Receive the CCS on the CMD line.†
- Send CCSD command—Sends the CCSD pattern (0b00001) on the CMD line.†

CCS Detection and Interrupt to Host Processor

If the `ccs_expected` bit in the `cmd` register is set to 1, the CCS from the CE-ATA card device is indicated by setting the data transfer over bit (`dto`) in the `rintsts` register. The controller generates a DTO interrupt if this interrupt is not masked.†

For the RW_MULTIPLE_BLOCK commands, if the CE-ATA card device interrupts are disabled (the `nIEN` bit is set to 1 in the ATA control register)— that is, the `ccs_expected` bit is set to 0 in the `cmd` register—there are no CCSs from the card. When the data transfer is over—that is, when the requested number of bytes are transferred—the `dto` bit in the `rintsts` register is set to 1.†

CCS Timeout

If the command expects a CCS from the card device (the `ccs_expected` bit is set to 1 in the `cmd` register), the command state machine waits for the CCS and remains in the wait CCS state. If the CE-ATA card fails to send out the CCS, the host software must implement a timeout mechanism to free the command and data path. The controller does not implement a hardware timer; it is the responsibility of the host software to maintain a software timer.[†]

In the event of a CCS timeout, the host must issue a CCSD command by setting the `send_ccsd` bit in the `ctrl` register. The controller command path state machine sends the CCSD command to the CE-ATA card device and exits to an idle state. After sending the CCSD command, the host must also send an SD/SDIO STOP_TRANSMISSION command to the CE-ATA card to abort the outstanding ATA command.[†]

Send CCSD Command

If the `send_ccsd` bit in the `ctrl` register is set to 1, the controller sends a CCSD pattern on the CMD line. The host can send the CCSD command while waiting for the CCS or after a CCS timeout happens.[†]

After sending the CCSD pattern, the controller sets the `cmd` bit in the `rintsts` register and also generates an interrupt to the host if the Command Done interrupt is not masked.[†]

Note: Within the CIU block, if the `send_ccsd` bit in the `ctrl` register is set to 1 on the same clock cycle as CCS is sampled, the CIU block does not send a CCSD pattern on the CMD line. In this case, the `dto` and `cmd` bits in the `rintsts` register are set to 1.[†]

Note: Due to asynchronous boundaries, the CCS might have already happened and the `send_ccsd` bit is set to 1. In this case, the CCSD command does not go to the CE-ATA card device and the `send_ccsd` bit is not set to 0. The host must reset the `send_ccsd` bit to 0 before the next command is issued.[†]

If the send auto stop CCSD (`send_auto_stop_ccsd`) bit in the `ctrl` register is set to 1, the controller sends an internally generated STOP_TRANSMISSION command (CMD12) after sending the CCSD pattern. The controller sets the `acd` bit in the `rintsts` register.[†]

I/O transmission delay (N_{ACIO} Timeout)

The host software maintains the timeout mechanism for handling the I/O transmission delay (N_{ACIO} cycles) time-outs while reading from the CE-ATA card device. The controller neither maintains any timeout mechanism nor indicates that N_{ACIO} cycles are elapsed while waiting for the start bit of a data token. The I/O transmission delay is applicable for read transfers using the RW_REG and RW_BLK commands; the RW_REG and RW_BLK commands used in this document refer to the RW_MULTIPLE_REGISTER and RW_MULTIPLE_BLOCK MMC commands defined by the CE-ATA specification.[†]

Note: After the N_{ACIO} timeout, the application must abort the command by sending the CCSD and STOP commands, or the STOP command. The Data Read Timeout (DRTO) interrupt might be set to 1 while a STOP_TRANSMISSION command is transmitted out of the controller, in which case the data read timeout boot data start bit (`bds`) and the `dto` bit in the `rintsts` register are set to 1.[†]

Data Path

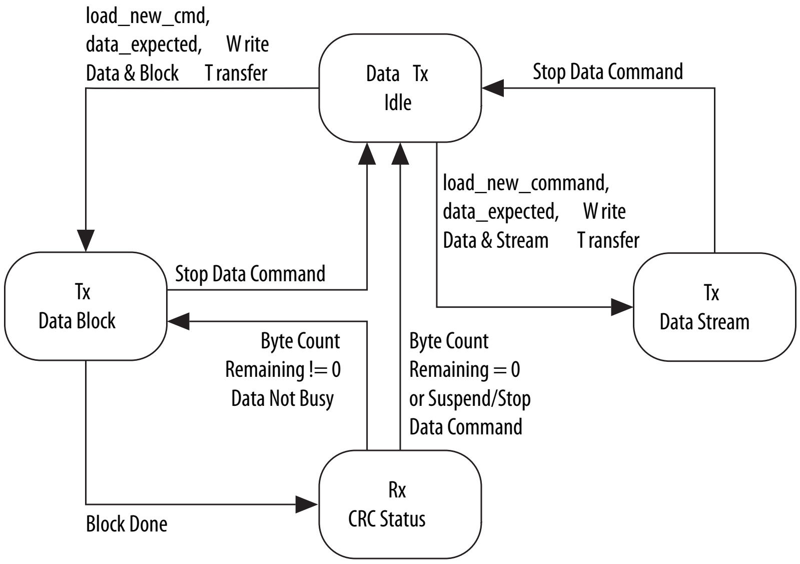
The data path block reads the data FIFO buffer and transmits data on the card bus during a write data transfer, or receives data and writes it to the FIFO buffer during a read data transfer. The data path loads new data parameters—data expected, read/write data transfer, stream/block transfer, block size, byte count, card type, timeout registers—whenever a data transfer command is not in progress. If the data transfer expected bit (`data_expected`) in the `cmd` register is set to 1, the new command is a data transfer command and the data path starts one of the following actions:[†]

- Transmits data if the read/write bit = 1[†]
- Receives data if read/write bit = 0[†]

Data Transmit

The data transmit state machine starts data transmission two clock cycles after a response for the data write command is received. This occurs even if the command path detects a response error or response CRC error. If a response is not received from the card because of a response timeout, data is not transmitted. Depending upon the value of the transfer mode bit (`transfer_mode`) in the `cmd` register, the data transmit state machine puts data on the card data bus in a stream or in blocks.†

Figure 14-9: Data Transmit State Machine†



Stream Data Transmit

If the `transfer_mode` bit in the `cmd` register is set to 1, the transfer is a stream-write data transfer. The data path reads data from the FIFO buffer from the BIU and transmits in a stream to the card data bus. If the FIFO buffer becomes empty, the card clock is stopped and restarted once data is available in the FIFO buffer.†

If the `bytcnt` register is reset to 0, the transfer is an open-ended stream-write data transfer. During this data transfer, the data path continuously transmits data in a stream until the host software issues an SD/SDIO STOP command. A stream data transfer is terminated when the end bit of the STOP command and end bit of the data match over two clock cycles.†

If the `bytcnt` register is written with a nonzero value and the `send_auto_stop` bit in the `cmd` register is set to 1, the STOP command is internally generated and loaded in the command path when the end bit of the STOP command occurs after the last byte of the stream write transfer matches. This data transfer can also terminate if the host issues a STOP command before all the data bytes are transferred to the card bus.†

Single Block Data

If the `transfer_mode` bit in the `cmd` register is set to 0 and the `bytcnt` register value is equal to the value of the `block_size` register, a single-block write-data transfer occurs. The data transmit state machine sends data in a single block, where the number of bytes equals the block size, including the internally-generated 16-term CRC (CRC-16).†

If the `ctype` register is set for a 1-bit, 4-bit, or 8-bit data transfer, the data is transmitted on 1, 4, or 8 data lines, respectively, and CRC-16 is separately generated and transmitted for 1, 4, or 8 data lines, respectively.†

After a single data block is transmitted, the data transmit state machine receives the CRC status from the card and signals a data transfer to the BIU. This happens when the dto bit in the rintsts register is set to 1.†

If a negative CRC status is received from the card, the data path signals a data CRC error to the BIU by setting the dcrc bit in the rintsts register.†

Additionally, if the start bit of the CRC status is not received by two clock cycles after the end of the data block, a CRC status start-bit error (SBE) is signaled to the BIU by setting the sbe bit in the rintsts register.†

Multiple Block Data

A multiple-block write-data transfer occurs if the transfer_mode bit in the cmd register is set to 0 and the value in the bytcnt register is not equal to the value of the block_size register. The data transmit state machine sends data in blocks, where the number of bytes in a block equals the block size, including the internally-generated CRC-16 value.†

If the ctype register is set to 1-bit, 4-bit, or 8-bit data transfer, the data is transmitted on 1, 4, or 8 data lines, respectively, and CRC-16 is separately generated and transmitted on 1, 4, or 8 data lines, respectively.†

After one data block is transmitted, the data transmit state machine receives the CRC status from the card. If the remaining byte count becomes 0, the data path signals to the BIU that the data transfer is done. This happens when the dto bit in the rintsts register is set to 1.†

If the remaining data bytes are greater than zero, the data path state machine starts to transmit another data block.†

If a negative CRC status is received from the card, the data path signals a data CRC error to the BIU by setting the dcrc bit in the rintsts register, and continues further data transmission until all the bytes are transmitted.†

If the CRC status start bit is not received by two clock cycles after the end of a data block, a CRC status SBE is signaled to the BIU by setting the ebe bit in the rintsts register and further data transfer is terminated.†

If the send_auto_stop bit is set to 1 in the cmd register, the SD/SDIO STOP command is internally generated during the transfer of the last data block, where no extra bytes are transferred to the card. The end bit of the STOP command might not exactly match the end bit of the CRC status in the last data block.†

If the block size is less than 4, 16, or 32 for card data widths of 1 bit, 4 bits, or 8 bits, respectively, the data transmit state machine terminates the data transfer when all the data is transferred, at which time the internally-generated STOP command is loaded in the command path.†

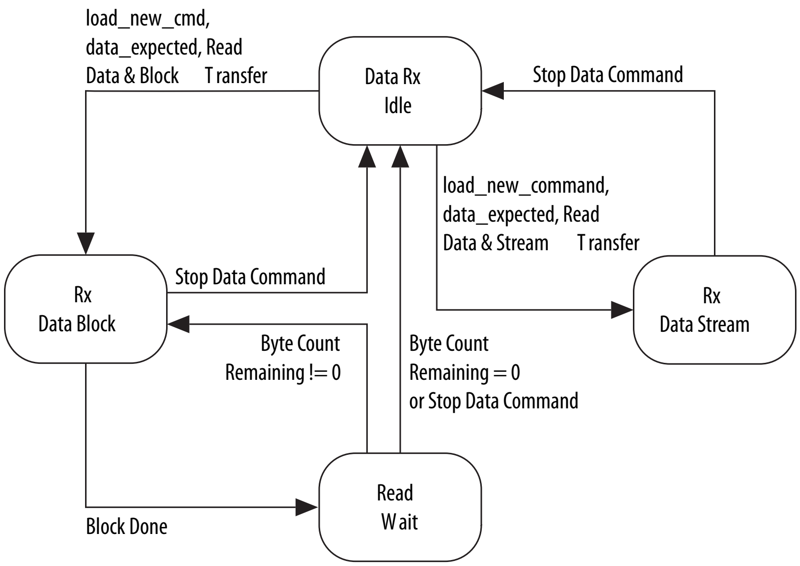
If the bytcnt is zero (the block size must be greater than zero) the transfer is an open-ended block transfer. The data transmit state machine for this type of data transfer continues the block-write data transfer until the host software issues an SD/SDIO STOP or STOP_TRANSMISSION (CMD12) command.†

Data Receive

The data-receive state machine receives data two clock cycles after the end bit of a data read command, even if the command path detects a response error or response CRC error. If a response is not received from the card because a response timeout occurs, the BIU does not receive a signal that the data transfer is complete. This happens if the command sent by the controller is an illegal operation for the card, which keeps the card from starting a read data transfer.†

If data is not received before the data timeout, the data path signals a data timeout to the BIU and an end to the data transfer done. Based on the value of the `transfer_mode` bit in the `cmd` register, the data-receive state machine gets data from the card data bus in a stream or block(s).†

Figure 14-10: Data Receive State Machine†



Stream Data Read

A stream-read data transfer occurs if the `transfer_mode` bit in the `cmd` register is set to 1, at which time the data path receives data from the card and writes it to the FIFO buffer. If the FIFO buffer becomes full, the card clock stops and restarts once the FIFO buffer is no longer full.†

An open-ended stream-read data transfer occurs if the `bytcnt` register is set to 0. During this type of data transfer, the data path continuously receives data in a stream until the host software issues an SD/SDIO STOP command. A stream data transfer terminates two clock cycles after the end bit of the STOP command.†

If the `bytcnt` register contains a nonzero value and the `send_auto_stop` bit in the `cmd` register is set to 1, a STOP command is internally generated and loaded into the command path, where the end bit of the STOP command occurs after the last byte of the stream data transfer is received. This data transfer can terminate if the host issues an SD/SDIO STOP or STOP_TRANSMISSION (CMD12) command before all the data bytes are received from the card.†

Single-block Data Read

If the `ctype` register is set to a 1-bit, 4-bit, or 8-bit data transfer, data is received from 1, 4, or 8 data lines, respectively, and CRC-16 is separately generated and checked for 1, 4, or 8 data lines, respectively. If there is a CRC-16 mismatch, the data path signals a data CRC error to the BIU. If the received end bit is not 1, the BIU receives an End-bit Error (EBE).†

Multiple-block Data Read

If the `transfer_mode` bit in the `cmd` register is set to 0 and the value of the `bytcnt` register is not equal to the value of the `block_size` register, the transfer is a multiple-block read-data transfer. The data-receive state machine receives data in blocks, where the number of bytes in a block is equal to the block size, including the internally-generated CRC-16.†

If the `ctype` register is set to a 1-bit, 4-bit, or 8-bit data transfer, data is received from 1, 4, or 8 data lines, respectively, and CRC-16 is separately generated and checked for 1, 4, or 8 data lines, respectively. After a data block is received, if the remaining byte count becomes zero, the data path signals a data transfer to the BIU.†

If the remaining data bytes are greater than zero, the data path state machine causes another data block to be received. If CRC-16 of a received data block does not match the internally-generated CRC-16, a data CRC error to the BIU and data reception continue further data transmission until all bytes are transmitted. Additionally, if the end of a received data block is not 1, data on the data path signals terminate the bit error to the CIU and the data-receive state machine terminates data reception, waits for data timeout, and signals to the BIU that the data transfer is complete.†

If the send_auto_stop bit in the cmd register is set to 1, the SD/SDIO STOP command is internally generated when the last data block is transferred, where no extra bytes are transferred from the card. The end bit of the STOP command might not exactly match the end bit of the last data block.†

If the requested block size for data transfers to cards is less than 4, 16, or 32 bytes for 1-bit, 4-bit, or 8-bit data transfer modes, respectively, the data-transmit state machine terminates the data transfer when all data is transferred, at which point the internally-generated STOP command is loaded in the command path. Data received from the card after that are then ignored by the data path.†

If the bytcnt register is 0 (the block size must be greater than zero), the transfer is an open-ended block transfer. For this type of data transfer, the data-receive state machine continues the block-read data transfer until the host software issues an SD/SDIO STOP or STOP_TRANSMISSION (CMD12) command.†

Auto-Stop

The controller internally generates an SD/SDIO STOP command and is loaded in the command path when the send_auto_stop bit in the cmd register is set to 1. The AUTO_STOP command helps to send an exact number of data bytes using a stream read or write for the MMC, and a multiple-block read or write for SD memory transfer for SD cards. The software must set the send_auto_stop bit according to the following details: †

The following list describes conditions for the AUTO_STOP command:†

- Stream-read for MMC with byte count greater than zero—The controller generates an internal STOP command and loads it into the command path so that the end bit of the STOP command is sent when the last byte of data is read from the card and no extra data byte is received. If the byte count is less than six (48 bits), a few extra data bytes are received from the card before the end bit of the STOP command is sent.†
- Stream-write for MMC with byte count greater than zero—The controller generates an internal STOP command and loads it into the command path so that the end bit of the STOP command is sent when the last byte of data is transmitted on the card bus and no extra data byte is transmitted. If the byte count is less than six (48 bits), the data path transmits the data last to meet these condition.†
- Multiple-block read memory for SD card with byte count greater than zero—If the block size is less than four (single-bit data bus), 16 (4-bit data bus), or 32 (8-bit data bus), the AUTO_STOP command is loaded in the command path after all the bytes are read. Otherwise, the STOP command is loaded in the command path so that the end bit of the STOP command is sent after the last data block is received.†
- Multiple-block write memory for SD card with byte count greater than zero—If the block size is less than three (single-bit data bus), 12 (4-bit data bus), or 24 (8-bit data bus), the AUTO_STOP command is loaded in the command path after all data blocks are transmitted. Otherwise, the STOP command is loaded in the command path so that the end bit of the STOP command is sent after the end bit of the CRC status is received.†
- Precaution for host software during auto-stop—When an AUTO_STOP command is issued, the host software must not issue a new command to the controller until the AUTO_STOP command is sent by the controller and the data transfer is complete. If the host issues a new command during a data transfer with the AUTO_STOP command in progress, an AUTO_STOP command might be sent after the new command is sent and its response is received. This can delay sending the STOP command, which transfers extra data bytes. For a stream write, extra data bytes are erroneous data that can corrupt the card data. If the host wants to terminate the data transfer before the data transfer is complete, it can issue an SD/SDIO STOP or STOP_TRANSMISSION (CMD12) command, in which case the controller does not generate an AUTO_STOP command.†

Auto-Stop Generation for MMC Cards

Table 14-11: Auto-Stop Generation for MMC Cards†

Transfer Type	Byte Count	send_auto_stop bit set	Comments
Stream read	0	No	Open-ended stream
Stream read	>0	Yes	Auto-stop after all bytes transfer
Stream write	0	No	Open-ended stream
Stream write	>0	Yes	Auto-stop after all bytes transfer
Single-block read	>0	No	Byte count = 0 is illegal
Single-block write	>0	No	Byte count = 0 is illegal
Multiple-block read	0	No	Open-ended multiple block
Multiple-block read	>0	Yes †	Pre-defined multiple block
Multiple-block write	0	No	Open-ended multiple block
Multiple-block write	>0	Yes †	Pre-defined multiple block

Auto-Stop Generation for SD Cards

Table 14-12: Auto-Stop Generation for SD Cards[†]

Transfer Type	Byte Count	send_auto_stop bit set	Comments
Single-block read	>0	No	Byte count = 0 is illegal
Single-block write	>0	No	Byte count = 0 illegal
Multiple-block read	0	No	Open-ended multiple block
Multiple-block read	>0	Yes	Auto-stop after all bytes transfer
Multiple-block write	0	No	Open-ended multiple block
Multiple-block write	>0	Yes	Auto-stop after all bytes transfer

Auto-Stop Generation for SDIO Cards

Table 14-13: Auto-Stop Generation for SDIO Cards[†]

Transfer Type	Byte Count	send_auto_stop bit set	Comments
Single-block read	>0	No	Byte count = 0 is illegal
Single-block write	>0	No	Byte count = 0 illegal
Multiple-block read	0	No	Open-ended multiple block
Multiple-block read	>0	No	Pre-defined multiple block
Multiple-block write	0	No	Open-ended multiple block
Multiple-block write	>0	No	Pre-defined multiple block

Non-Data Transfer Commands that Use Data Path

Some SD/SDIO non-data transfer commands (commands other than read and write commands) also use the data path.[†]

[37] The condition under which the transfer mode is set to block transfer and byte_count is equal to block size is treated as a single-block data transfer command for both MMC and SD cards. If byte_count = n*block_size (n = 2, 3, …), the condition is treated as a predefined multiple-block data transfer command. In the case of an MMC card, the host software can perform a predefined data transfer in two ways: 1) Issue the CMD23 command before issuing CMD18/CMD25 commands to the card – in this case, issue CMD18/CMD25 commands without setting the send_auto_stop bit. 2) Issue CMD18/CMD25 commands without issuing CMD23 command to the card, with the send_auto_stop bit set. In this case, the multiple-block data transfer is terminated by an internally-generated auto-stop command after the programmed byte count.[†]

Table 14-14: Non-Data Transfer Commands and Requirements†

	PROGRAM_ CSD (CMD27)	SEND_ WRITE_PROT (CMD30)	LOCK_ UNLOCK (CMD42)	SD_ STATUS (ACMD13)	SEND_NUM_ WR_BLOCKS (ACMD22)	SEND_SCR (ACMD51)

Clock Control Block

The clock control block provides different clock frequencies required for SD/MMC/CE-ATA cards. The clock control block has one clock divider, which is used to generate different card clock frequencies.†

The clock frequency of a card depends on the following clock `ctrl` register settings:†

- `clkdiv` register—Internal clock dividers are used to generate different clock frequencies required for the cards. The division factor for the clock divider can be set by writing to the `clkdiv` register. The clock divider is an 8-bit value that provides a clock division factor from 1 to 510; a value of 0 represents a clock-divider bypass, a value of 1 represents a divide by 2, a value of 2 represents a divide by 4, and so on.†
- `clksrc` register—Set this register to 0 as clock is divided by clock divider 0.†
- `clkena` register—The `cclk_out` card output clock can be enabled or disabled under the following conditions:†
    - `cclk_out` is enabled when the `cclk_enable` bit in the `clkena` register is set to 1 and disabled when set to 0.†
    - Low-power mode can be enabled by setting the `cclk_low_power` bit of the `clkena` register to 1. If low-power mode is enabled to save card power, the `cclk_out` signal is disabled when the card is idle for at least eight card clock cycles. Low-power mode is enabled when a new command is loaded and the command path goes to a non-idle state.†

Under the following conditions, the card clock is stopped or disabled:†

- Clock can be disabled by writing to the `clkena` register.†
- When low-power mode is selected and the card is idle for at least eight clock cycles.†
- FIFO buffer is full, data path cannot accept more data from the card, and data transfer is incomplete—to avoid FIFO buffer overflow.†
- FIFO buffer is empty, data path cannot transmit more data to the card, and data transfer is incomplete—to avoid FIFO buffer underflow.†

Note: The card clock must be disabled through the `clkena` register before the host software changes the values of the `clkdiv` and `clksrc` registers.†

Error Detection

Errors can occur during card operations within the CIU in the following situations.

Response†

- Response timeout—did not receive the response expected with response start bit within the specified number of clock cycles in the timeout register.†
- Response CRC error—response is expected and check response CRC requested; response CRC-7 does not match with the internally-generated CRC-7.†
- Response error—response transmission bit is not 0, command index does not match with the command index of the send command, or response end bit is not 1.†

Data Transmit†

- No CRC status—during a write data transfer, if the CRC status start bit is not received for two clock cycles after the end bit of the data block is sent out, the data path performs the following actions:†
  - Signals no CRC status error to the BIU†
  - Terminates further data transfer†
  - Signals data transfer done to the BIU†
- Negative CRC—if the CRC status received after the write data block is negative (that is, not 0b010), the data path signals a data CRC error to the BIU and continues with the data transfer.†
- Data starvation due to empty FIFO buffer—if the FIFO buffer becomes empty during a write data transmission, or if the card clock stopped and the FIFO buffer remains empty for a data-timeout number of clock cycles, the data path signals a data-starvation error to the BIU and the data path continues to wait for data in the FIFO buffer.†

Data Receive

- Data timeout—during a read-data transfer, if the data start bit is not received before the number of clock cycles specified in the timeout register, the data path does the following action: †
  - Signals a data-timeout error to the BIU†
  - Terminates further data transfer†
  - Signals data transfer done to BIU†
- Data SBE—during a 4-bit or 8-bit read-data transfer, if the all-bit data line does not have a start bit, the data path signals a data SBE to the BIU and waits for a data timeout, after which it signals that the data transfer is done.†
- Data CRC error—during a read-data-block transfer, if the CRC-16 received does not match with the internally generated CRC-16, the data path signals a data CRC error to the BIU and continues with the data transfer.†
- Data EBE—during a read-data transfer, if the end bit of the received data is not 1, the data path signals an EBE to the BIU, terminates further data transfer, and signals to the BIU that the data transfer is done.†
- Data starvation due to FIFO buffer full—during a read data transmission and when the FIFO buffer becomes full, the card clock stops. If the FIFO buffer remains full for a data-timeout number of clock cycles, the data path signals a data starvation error to the BIU, by setting the data starvation host timeout bit (hto) in rintsts register to 1, and the data path continues to wait for the FIFO buffer to empty.†

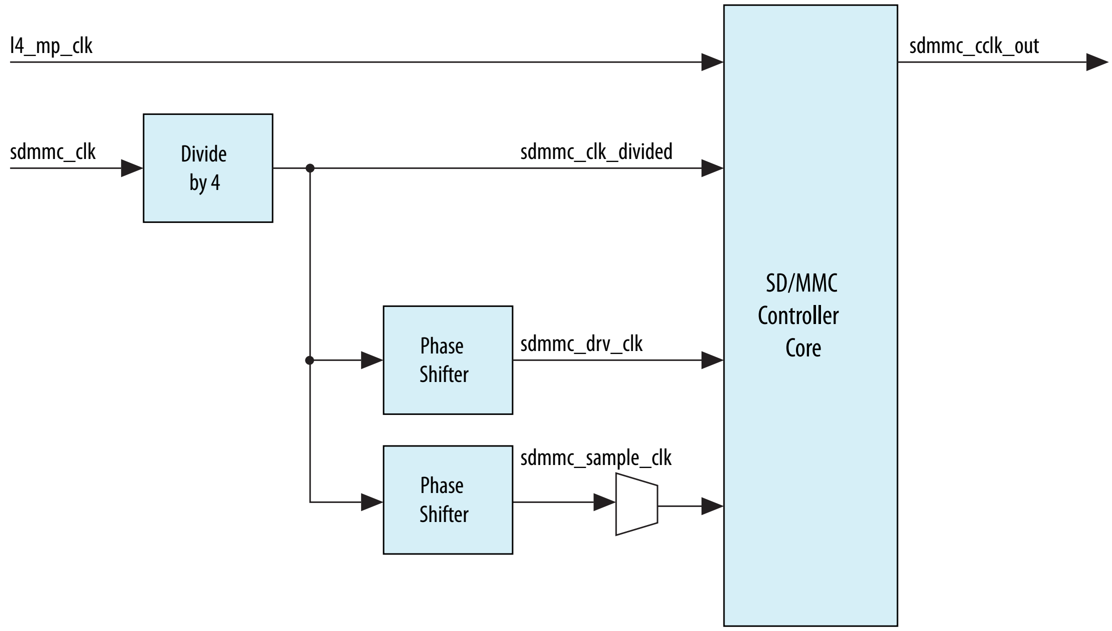
Clocks

Table 14-15: SD/MMC Controller Clocks

Clock Name	Direction	Description
l4_mp_clk	In	Clock for SD/MMC controller BIU
sdmmc_clk	In	Clock for SD/MMC controller
sdmmc_cclk_out	Out	Generated output clock for card
sdmmc_clk_divided	Internal	Divide-by-four clock of sdmmc_clk

Clock Name	Direction	Description
`sdmmc_sample_clk`	Internal	Phase-shifted clock of `sdmmc_clk_divided` used to sample the command and data from the card
`sdmmc_drv_clk`	Internal	Phase-shifted clock of `sdmmc_clk_divided` for controller to drive command and data to the card to meet hold time requirements

Figure 14-11: SD/MMC Controller Clock Connections



The *sdmmc_clk* clock from the clock manager is divided by four and becomes the *sdmmc_clk_divided* clock before passing to the phase shifters and the SD/MMC controller CIU. The phase shifters are used to generate the *sdmmc_drv_clk* and *sdmmc_sample_clk* clocks. These phase shifters provide up to eight phases shift which include 0, 45, 90, 135, 180, 225, 270, and 315 degrees. The *sdmmc_sample_clk* clock can be driven by the output from the phase shifter.

Note: The selections of phase shift degree and *sdmmc_sample_clk* source are done in the system manager. For information about setting the phase shift and selecting the source of the *sdmmc_sample_clk* clock, refer to the *Clock Setup* section within this document.

The controller generates the *sdmmc_cclk_out* clock, which is driven to the card. For more information about the generation of the *sdmmc_cclk_out* clock, refer to the *Clock Control Block* section within this document.

  Refer to this section for information about the generation of the `sdmmc_cclk_out`clock.

Resets

The SD/MMC controller has one reset signal. The reset manager drives this signal to the SD/MMC controller on a cold or warm reset.

Related Information

Reset Manager on page 3-1

Interface Signals

Table 14-16: SD/MMC Controller Interface I/O Pins

Signal	Width	Direction	Description
`sdmmc_cclk_out`	1	Out	Clock from controller to the card
`sdmmc_cmd`	1	In/Out	Card command
`sdmmc_pwren`	1	Out	External device power enable
`sdmmc_data`	8	In/Out	Card data

SD/MMC Controller Programming Model

Software and Hardware Restrictions†

Only one data transfer command should be issued at one time. For CE-ATA devices, if CE-ATA device interrupts are enabled (nIEN=0), only one RW_MULTIPLE_BLOCK command (RW_BLK) should be issued; no other commands (including a new RW_BLK) should be issued before the Data Transfer Over status is set for the outstanding RW_BLK.†

Before issuing a new data transfer command, the software should ensure that the card is not busy due to any previous data transfer command. Before changing the card clock frequency, the software must ensure that there are no data or command transfers in progress.†

If the card is enumerated in SDR50, SDR104, or DDR50 mode, then the application must program the use_hold_reg bit[29] in the CMD register to 1’b0 (phase shift of cclk_in_drv = 0) or 1'b1 (phase shift of cclk_in_drv > 0). If the card is enumerated in SDR12 or SDR25 mode, the application must program the use_hold_reg bit[29] in the CMD register to 1’b1.†

This programming should be done for all data transfer commands and non-data commands that are sent to the card. When the use_hold_reg bit is programmed to 1’b0, the DWC_mobile_storage bypasses the Hold Registers in the transmit path. The value of this bit should not be changed when a Command or Data Transfer is in progress.†

For more information on using the `use_hold_reg` and the implementation requirements for meeting the card input hold time, refer to the latest version of the Synopsys DesignWare Cores Mobile Storage Host Databook.

Avoiding Glitches in the Card Clock Outputs†

To avoid glitches in the card clock outputs (`cclk_out`), the software should use the following steps when changing the card clock frequency:†

1. Before disabling the clocks, ensure that the card is not busy due to any previous data command. To determine this, check for 0 in bit 9 of the STATUS register.†
2. Update the Clock Enable register to disable all clocks. To ensure completion of any previous command before this update, send a command to the CIU to update the clock registers by setting:†

   - `start_cmd` bit†
   - "update clock registers only" bits†
   - "wait_previous data complete"†

   Note: Wait for the CIU to take the command by polling for 0 on the `start_cmd` bit.†
3. Set the `start_cmd` bit to update the Clock Divider and/or Clock Source registers, and send a command to the CIU in order to update the clock registers; wait for the CIU to take the command.†
4. Set `start_cmd` to update the Clock Enable register in order to enable the required clocks and send a command to the CIU to update the clock registers; wait for the CIU to take the command.†

Reading from a Card in Non-DMA Mode†

In non-DMA mode, while reading from a card, the Data Transfer Over (RINTSTS[3]) interrupt occurs as soon as the data transfer from the card is over. There still could be some data left in the FIFO, and the RX_WMark interrupt may or may not occur, depending on the remaining bytes in the FIFO. Software should read any remaining bytes upon seeing the Data Transfer Over (DTO) interrupt. While using the external DMA interface for reading from a card, the DTO interrupt occurs only after all the data is flushed to memory by the DMA Interface unit.†

Writing to a Card in External DMA Mode†

While writing to a card in external DMA mode, if an undefined-length transfer is selected by setting the Byte Count register to 0, the DMA logic will likely request more data than it will send to the card, since it has no way of knowing at which point the software will stop the transfer. The DMA request stops as soon as the DTO is set by the CIU.†

Software Issues a `Controller_Reset` Command†

If the software issues a `controller_reset` command by setting control register bit[0] to 1, all the CIU state machines are reset; the FIFO is not cleared. The DMA sends all remaining bytes to the host. In addition to a card-reset, if a FIFO reset is also issued, then:†

- Any pending DMA transfer on the bus completes correctly†
- DMA data read is ignored†
- Write data is unknown (x)†

Additionally, if dma_reset is also issued, any pending DMA transfer is abruptly terminated. When the DW-DMA/Non-DW-DMA is used, the DMA controller channel should also be reset and reprogrammed.†

If any of the previous data commands do not properly terminate, then the software should issue the FIFO reset in order to remove any residual data, if any, in the FIFO. After asserting the FIFO reset, you should wait until this bit is cleared.†

Data-Transfer Requirement Between the FIFO and Host†

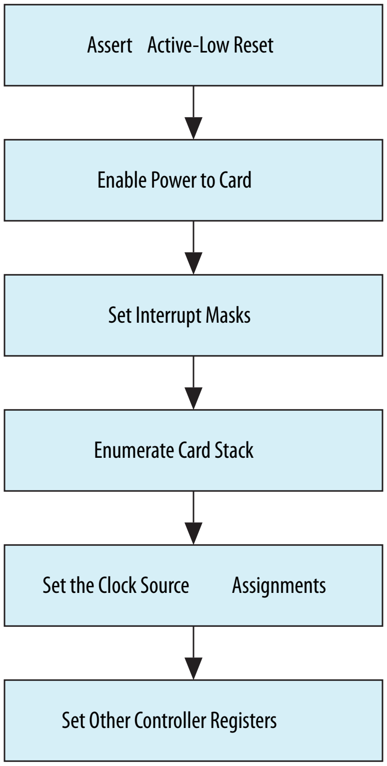
One data-transfer requirement between the FIFO and host is that the number of transfers should be a multiple of the FIFO data width (F_DATA_WIDTH). For example, if F_DATA_WIDTH = 32 and you want to write only 15 bytes to an SD_MMC_CEATA card (BYTCNT), the host should write 16 bytes to the FIFO or program the DMA to do 16-byte transfers, if external DMA mode is enabled. The software can still program the Byte Count register to only 15, at which point only 15 bytes will be transferred to the card. Similarly, when 15 bytes are read from a card, the host should still read all 16 bytes from the FIFO.†

It is recommended that you not change the FIFO threshold register in the middle of data transfers when DW-DMA/Non-DW-DMA mode is chosen.†

Initialization†

After the power and clock to the controller are stable, the controller active-low reset is asserted. The reset sequence initializes the registers, FIFO buffer pointers, DMA interface controls, and state machines in the controller.†

Figure 14-12: SD/MMC Controller Initialization Sequence†



Power-On Reset Sequence

Software must perform the following steps after the power-on-reset:

1. Before enabling power to the card, confirm that the voltage setting to the voltage regulator is correct. †
2. Enable power to the card by setting the power enable bit (power_enable) in the power enable register (pwren) to 1. Wait for the power ramp-up time before proceeding to the next step.†
3. Set the interrupt masks by resetting the appropriate bits to 0 in the intmask register.†
4. Set the int_enable bit of the ctrl register to 1.†

Note: Altera recommends that you write 0xFFFFFFFF to the `rintsts` register to clear any pending interrupts before setting the `int_enable` bit to 1.†

5. Discover the card stack according to the card type. For discovery, you must restrict the clock frequency to 400 kHz in accordance with SD/MMC/CE-ATA standards. For more information, refer to *Enumerated Card Stack*.†
6. Set the clock source assignments. Set the card frequency using the `clkdiv` and `clksrc` registers of the controller. For more information, refer to *Clock Setup*.†
7. The following common registers and fields can be set during initialization process:†
    - The response timeout field (`response_timeout`) of the `tmout` register. A typical value is 0x64.†
    - The data timeout field (`data_timeout`) of the `tmout` register, highest of the following:†
        - 10 * N_{AC} †

          N_{AC} = card device total access time†

          = 10 * ((TAAC * F_{OP}) + (100 * NSAC))†

          where:†

          TAAC = Time-dependent factor of the data access time†

          F_{OP} = The card clock frequency used for the card operation†

          NSAC = Worst-case clock rate-dependent factor of the data access time†
        - Host FIFO buffer latency†

          On read: Time elapsed before host starts reading from a full FIFO buffer†

          On write: Time elapsed before host starts writing to an empty FIFO buffer†
    - Debounce counter register (`debnce`). A typical debounce value is 25 ms.†
    - TX watermark field (`tx_wmark`) of the FIFO threshold watermark register (`fifoth`). Typically, the threshold value is set to 512, which is half the FIFO buffer depth.†
    - RX watermark field (`rx_wmark`) of the `fifoth` register. Typically, the threshold value is set to 511.†

These registers do not need to be changed with every SD/MMC/CE-ATA command. Set them to a typical value according to the SD/MMC/CE-ATA specifications.

Related Information

- **Clock Setup** on page 14-41
  Refer to this section for information on setting the clock source assignments.
- **Enumerated Card Stack** on page 14-38
  Refer to this section for information on discovering the card stack according to the card type.

Enumerated Card Stack

The card stack performs the following tasks:

- Discovers the connected card †
- Sets the relative Card Address Register (RCA) in the connected card†
- Reads the card specific information†
- Stores the card specific information locally†

The card connected to the controller can be an MMC, CE-ATA, SD or SDIO (including IO ONLY, MEM ONLY and COMBO) card.

Identifying the Connected Card Type

To identify the connected card type, the following discovery sequence is needed:

1. Reset the card width 1 or 4 bit (`card_width2`) and card width 8 bit (`card_width1`) fields in the `ctype` register to 0.
2. Identify the card type as SD, MMC, SDIO or SDIO-COMBO:
    a. Send an SD/SDIO IO_SEND_OP_COND (CMD5) command with argument 0 to the card.
    b. Read `resp0` on the controller. The response to the IO_SEND_OP_COND command gives the voltage that the card supports.
    c. Send the IO_SEND_OP_COND command, with the desired voltage window in the arguments. This command sets the voltage window and makes the card exit the initialization state.
    d. Check bit 27 in `resp0`:
        - If bit 27 is 0, the SDIO card is IO ONLY. In this case, proceed to **step 5**.
        - If bit 27 is 1, the card type is SDIO COMBO. Continue with the following steps.
3. Only continue with this step if the SDIO card type is COMBO or there is no response received from the previous IO_SEND_OP_COND command. Otherwise, skip to **step 5**.
    a. Send the SD/SDIO SEND_IF_COND (CMD8) command with the following arguments:
        - Bit[31:12] = 0x0 (reserved bits)†
        - Bit[11:8] = 0x1 (supply voltage value)†
        - Bit[7:0] = 0xAA (preferred check pattern by SD memory cards compliant with SDIO Simplified Specification Version 2.00 and later.)†

       Refer to *SDIO Simplified Specification Version 2.00* as described on the SD Association website.
    b. If a response is received to the previous SEND_IF_COND command, the card supports SD High-Capacity, compliant with SD Specifications, Part 1, Physical Layer Simplified Specification Version 2.00.

       If no response is received, proceed to **step e**.
    c. Send the SD_SEND_OP_COND (ACMD41) command with the following arguments:
        - Bit[31] = 0x0 (reserved bits)†
        - Bit[30] = 0x1 (high capacity status)†
        - Bit[29:25] = 0x0 (reserved bits)†
        - Bit[24] = 0x1 (S18R --supports voltage switching for 1.8V)†
        - Bit[23:0] = supported voltage range†
    d. If a response is received to the previous SD_SEND_OP_COND command, the card type is SDHC. Otherwise, the card is MMC or CE-ATA. In either case, skip the following steps and proceed to **step 5**.
    e. If a response is not received to the initial SEND_IF_COND command, the card does not support High Capacity SD2.0. Next, issue the GO_IDLE_STATE command followed by the SD_SEND_OP_COND command with the following arguments:
        - Bit[31] = 0x0 (reserved bits)†
        - Bit[30] = 0x0 (high capacity status)†
        - Bit[29:24] = 0x0 (reserved bits)†
        - Bit[23:0] = supported voltage range†
    f. If a response is received to the previous SD_SEND_OP_COND command, the card is SD type. Otherwise, the card is MMC or CE-ATA.

       Note: You must issue the SEND_IF_COND command prior to the first SD_SEND_OP_COND command, to initialize the High Capacity SD memory card. The card returns busy as a response to the SD_SEND_OP_COND command when any of the following conditions are true:

- The card executes its internal initialization process.
- A SEND_IF_COND command is not issued before the SD_SEND_OP_COND command.
- The ACMD41 command is issued. In the command argument, the Host Capacity Support (HCS) bit is set to 0, for a high capacity SD card.

4. Use the following sequence to determine whether the card is a CE-ATA 1.1, CE-ATA 1.0, or MMC device:

   a. Determine whether the card is a CE-ATA v1.1 card device by attempting to select ATA mode. Send the SD/SDIO SEND_IF_COND command, querying byte 504 (S_CMD_SET) of the EXT_CSD register block in the external card.

   - If bit 4 is set to 1, the card device supports ATA mode. Send the SWITCH_FUNC (CMD6) command, setting the ATA bit (bit 4) of the EXT_CSD register slice 191 (CMD_SET) to 1. This command selects ATA mode and activates the ATA command set.

     You can verify the currently selected mode by reading it back from byte 191 of the EXT_CSD register.

     Skip to **step 5**.
   - If the card device does not support ATA mode, it might be an MMC card or a CE-ATA v1.0 card. Continue to **Step b**.

   b. Determine whether the card is a CE-ATA 1.0 card device or an MMC card device by sending the RW_REG command. If a response is received and the response data contains the CE-ATA signature, the card is a CE-ATA 1.0 card device. Otherwise, the card is an MMC card device.
5. At this point, the software has determined the card type as SD/SDHC, SDIO or SDIO-COMBO. Now it must enumerate the card stack according to the type that has been discovered.
6. Set the card clock source frequency to the frequency of identification clock rate, 400 KHz. Use one of the following discovery command sequences:

   - For an SD card or an SDIO memory section, send the following SD/SDIO command sequence:

     - GO_IDLE_STATE
     - SEND_IF_COND
     - SD_SEND_OP_COND (ACMD41)
     - ALL_SEND_CID (CMD2)
     - SEND_RELATIVE_ADDR (CMD3)
   - For an SDIO card, send the following command sequence:

     - IO_SEND_OP_COND.
     - If the function count is valid, send the SEND_RELATIVE_ADDR command.
   - For an MMC, send the following command sequence:

     - GO_IDLE_STATE
     - SEND_OP_COND (CMD1)
     - ALL_SEND_CID
     - SEND_RELATIVE_ADDR
7. You can change the card clock frequency after discovery by writing a value to the `clkdiv` register that divides down the `sdmmc_clk` clock.

The following list shows typical clock frequencies for various types of cards:

- SD memory card, 25 MHz†
- MMC card device, 12.5 MHz†
- Full speed SDIO, 25 MHz†
- Low speed SDIO, 400 kHz†

Related Information

www.sdcard.org
To learn more about how SD technology works, visit the SD Association website.

Clock Setup

The following registers of the SD/MMC controller allow software to select the desired clock frequency for the card:

- `clksrc`
- `clkdiv`
- `clkena`

The controller loads these registers when it receives an update clocks command.

Changing the Card Clock Frequency

To change the card clock frequency, perform the following steps:

1. Before disabling the clocks, ensure that the card is not busy with any previous data command. To do so, verify that the `data_busy` bit of the status register (`status`) is 0.
2. Reset the `cclk_enable` bit of the `clkena` register to 0, to disable the card clock generation.
3. Reset the `clksrc` register to 0.
4. Set the following bits in the `cmd` register to 1:
   - `update_clk_regs_only`—Specifies the update clocks command†
   - `wait_prvdata_complete`—Ensures that clock parameters do not change until any ongoing data transfer is complete†
   - `start_cmd`—Initiates the command†
5. Wait until the `start_cmd` and `update_clk_regs_only` bits change to 0. There is no interrupt when the clock modification completes. The controller does not set the `command_done` bit in the `rintsts` register upon command completion. The controller might signal a hardware lock error if it already has another command in the queue. In this case, return to **Step 4**.

   For information about hardware lock errors, refer to *Interrupt and Error Handling*.
6. Reset the `sdmmc_clk_enable` bit to 0 in the `enable` register of the clock manager peripheral PLL group (`perpllgrp`).
7. In the control register (`ctrl`) of the SDMMC controller group (`sdmmcgrp`) in the system manager, set the drive clock phase shift select (`drvsel`) and sample clock phase shift select (`smplsel`) bits to specify the required phase shift value.
8. Set the `sdmmc_clk_enable` bit in the `Enable` register of the clock manager `perpllgrp` group to 1.
9. Set the `clkdiv` register of the controller to the correct divider value for the required clock frequency.
10. Set the `cclk_enable` bit of the `clkena` register to 1, to enable the card clock generation.

You can also use the clkena register to enable low-power mode, which automatically stops the sdmmc_cclk_out clock when the card is idle for more than eight clock cycles.

Interrupt and Error Handling on page 14-68
Refer to this section for information about hardware lock errors.

Controller/DMA/FIFO Buffer Reset Usage

The following list shows the effect of reset on various parts in the SD/MMC controller:†

- Controller reset—resets the controller by setting the controller_reset bit in the ctrl register to 1. Controller reset resets the CIU and state machines, and also resets the BIU-to-CIU interface. Because this reset bit is self-clearing, after issuing the reset, wait until this bit changes to 0.†
- FIFO buffer reset—resets the FIFO buffer by setting the FIFO reset bit (fifo_reset) in the ctrl register to 1. FIFO buffer reset resets the FIFO buffer pointers and counters in the FIFO buffer. Because this reset bit is self-clearing, after issuing the reset, wait until this bit changes to 0.†
- DMA reset—resets the internal DMA controller logic by setting the DMA reset bit (dma_reset) in the ctrl register to 1, which immediately terminates any DMA transfer in progress. Because this reset bit is self-clearing, after issuing the reset, wait until this bit changes to 0.†

Note: Ensure that the DMA is idle before performing a DMA reset. Otherwise, the L3 interconnect might be left in an indeterminate state.†

Altera recommends setting the controller_reset, fifo_reset, and dma_reset bits in the ctrl register to 1 first, and then resetting the rintsts register to 0 using another write, to clear any resultant interrupt.

Enabling FIFO Buffer ECC

To protect the FIFO buffer data with ECC, you must enable the ECC feature before performing any operations with the SD/MMC controller. Perform the following steps to enable the FIFO buffer ECC feature:

1. Verify there are no commands committed to the controller.
2. Ensure that the FIFO buffer is initialized. Initialize the FIFO buffer by writing 0 to all 1024 FIFO buffer locations. A FIFO buffer write to any address from 0x200 to the maximum FIFO buffer size is valid.
3. Set the SDMMC RAM ECC single and double, correctable error interrupt status bits (serrporta, derrporta, serrportb, and derrportb) to 1 in the sdmmc register in the eccgrp group of the system manager, to clear any previously-detected ECC errors.
4. Reset the FIFO buffer by setting the fifo_reset bit to 1 in the ctrl register. This action resets pointers and counters in the FIFO buffer. This reset bit is self-clearing, so after issuing the reset, wait until the bit changes to 0.
5. Set the en bit in sdmmc register in eccgrp group of the system manager to 1, to enable ECC for the FIFO buffer in SD/MMC controller.

Non-Data Transfer Commands

To send any non-data transfer command, the software needs to write the cmd register and the cmdarg register with appropriate parameters. Using these two registers, the controller forms the command and sends it to the CMD pin. The controller reports errors in the command response through the error bits of the rintsts register.†

When a response is received—either erroneous or valid—the controller sets the command_done bit in the rintsts register to 1. A short response is copied to resp0, while a long response is copied to all four response registers (resp0, resp1, resp2, and resp3).† For long responses, bit 31 of resp3 represents the MSB and bit 0 of resp0 represents the LSB.†

For basic and non-data transfer commands, perform the following steps:

1. Write the cmdarg register with the appropriate command argument parameter.†
2. Write the cmd register with the settings in *Register Settings for Non-Data Transfer Command*.†
3. Wait for the controller to accept the command. The start_cmd bit changes to 0 when the command is accepted.†

   The following actions occur when the command is loaded into the controller:†

   - If no previous command is being processed, the controller accepts the command for execution and resets the start_cmd bit in the cmd register to 0. If a previous command is being processed, the controller loads the new command in the command buffer.†
   - If the controller is unable to load the new command—that is, a command is already in progress, a second command is in the buffer, and a third command is attempted—the controller generates a hardware lock error.†
4. Check if there is a hardware lock error.†
5. Wait for command execution to complete. After receiving either a response from a card or response timeout, the controller sets the command_done bit in the rintsts register to 1. Software can either poll for this bit or respond to a generated interrupt (if enabled).†
6. Check if the response timeout boot acknowledge received (bar), rcrc, or re bit is set to 1. Software can either respond to an interrupt raised by these errors or poll the re, rcrc, and bar bits of the rintsts register. If no response error is received, the response is valid. If required, software can copy the response from the response registers.†

Note: Software cannot modify clock parameters while a command is being executed.†

Related Information

cmd Register Settings for Non-Data Transfer Command† on page 14-43
Refer to this table for information about Non-Data Transfer commands.

cmd Register Settings for Non-Data Transfer Command†

Table 14-17: Default

Parameter	Value	Comment
start_cmd	1	This bit resets itself to 0 after the command is committed.
use_hold_reg	1 or 0	Choose the value based on the speed mode used.
update_clk_regs_only	0	Indicates that the command is not a clock update command
data_expected	0	Indicates that the command is not a data command
card_number	1	For one card

Parameter	Value	Comment
`cmd_index`	Command Index	Set this parameter to the command number. For example, set to 8 for the SD/SDIO SEND_IF_COND (CMD8) command.
`send_initialization`	0 or 1	1 for card reset commands such as the SD/SDIO GO_IDLE_STATE command 0 otherwise
`stop_abort_cmd`	0 or 1	1 for a command to stop data transfer, such as the SD/SDIO STOP_TRANSMISSION command 0 otherwise
`response_length`	0 or 1	1 for R2 (long) response 0 for short response
`response_expect`	0 or 1	0 for commands with no response, such as SD/SDIO GO_IDLE_STATE, SET_DSR (CMD4), or GO_INACTIVE_STATE (CMD15). 1 otherwise

Table 14-18: User Selectable

Parameter	Value	Comment
`wait_prvdata_complete`	1	Before sending a command on the command line, the host must wait for completion of any data command already in process. Altera recommends that you set this bit to 1, unless the current command is to query status or stop data transfer when transfer is in progress.
`check_response_crc`	1 or 0	1 if the response includes a valid CRC, and the software is required to crosscheck the response CRC bits. 0 otherwise

Data Transfer Commands

Data transfer commands transfer data between the memory card and the controller. To issue a data command, the controller requires a command argument, total data size, and block size. Data transferred to or from the memory card is buffered by the controller FIFO buffer.†

Confirming Transfer State

Before issuing a data transfer command, software must confirm that the card is not busy and is in a transfer state, by performing the following steps:†

1. Issue an SD/SDIO SEND_STATUS (CMD13) command. The controller sends the status of the card as the response to the command.†
2. Check the card's busy status.†
3. Wait until the card is not busy.†
4. Check the card's transfer status. If the card is in the stand-by state, issue an SD/SDIO SELECT/DESELECT_CARD (CMD7) command to place it in the transfer state.†

Busy Signal After CE-ATA RW_BLK Write Transfer

During CE-ATA RW_BLK write transfers, the MMC busy signal might be asserted after the last block. If the CE-ATA card device interrupt is disabled (the nIEN bit in the card device's ATA control register is set to 1), the `dto` bit in the `rintsts` register is set to 1 even though the card sends MMC BUSY. The host cannot issue the CMD60 command to check the ATA busy status after a CMD61 command. Instead, the host must perform one of the following actions:†

- Issue the SEND_STATUS command and check the MMC busy status before issuing a new CMD60 command†
- Issue the CMD39 command and check the ATA busy status before issuing a new CMD60 command†

For the data transfer commands, software must set the `ctype` register to the bus width that is programmed in the card.†

Data Transfer Interrupts

The controller generates an interrupt for different conditions during data transfer, which are reflected in the following `rintsts` register bits:†

1. `dto`—Data transfer is over or terminated. If there is a response timeout error, the controller does not attempt any data transfer and the Data Transfer Over bit is never set.†
2. Transmit FIFO data request bit (`txdr`)—The FIFO buffer threshold for transmitting data is reached; software is expected to write data, if available, into the FIFO buffer.†
3. Receive FIFO data request bit (`rxdr`)—The FIFO buffer threshold for receiving data is reached; software is expected to read data from the FIFO buffer.†
4. `hto`—The FIFO buffer is empty during transmission or is full during reception. Unless software corrects this condition by writing data for empty condition, or reading data for full condition, the controller cannot continue with data transfer. The clock to the card is stopped.†
5. `bds`—The card has not sent data within the timeout period.†
6. `dcrc`—A CRC error occurred during data reception.†
7. `sbe`—The start bit is not received during data reception.†
8. `ebe`—The end bit is not received during data reception, or for a write operation. A CRC error is indicated by the card.†

`dcrc`, `sbe`, and `ebe` indicate that the received data might have errors. If there is a response timeout, no data transfer occurs.†

Single-Block or Multiple-Block Read

To implement a single-block or multiple-block read, the software performs the following steps:†

1. Write the data size in bytes to the `bytcnt` register. For a multi-block read, `bytcnt` must be a multiple of the block size.†
2. Write the block size in bytes to the `blksiz` register. The controller expects data to return from the card in blocks of size `blksiz`.†
3. If the read round trip delay, including the card delay, is greater than half of `sdmmc_clk_divided`, write to the card threshold control register (`cardthrctl`) to ensure that the card clock does not stop in the

middle of a block of data being transferred from the card to the host. For more information, refer to *Card Read Threshold*.†

Note: If the card read threshold enable bit (cardrdthren) is 0, the host system must ensure that the RX FIFO buffer does not become full during a read data transfer by ensuring that the RX FIFO buffer is read at a rate faster than that at which data is written into the FIFO buffer. Otherwise, an overflow might occur.†

4. Write the cmdarg register with the beginning data address for the data read.†
5. Write the cmd register with the parameters listed in *cmd Register Settings for Single-Block and Multiple-Block Reads*. For SD and MMC cards, use the SD/SDIO READ_SINGLE_BLOCK (CMD17) command for a single-block read and the READ_MULTIPLE_BLOCK (CMD18) command for a multiple-block read. For SDIO cards, use the IO_RW_EXTENDED (CMD53) command for both single-block and multiple-block transfers. The command argument for (CMD53) is shown in the figure, below. After writing to the cmd register, the controller starts executing the command. When the command is sent to the bus, the Command Done interrupt is generated.†
6. Software must check for data error interrupts, reported in the dcrc, bds, sbe, and ebe bits of the rintsts register. If required, software can terminate the data transfer by sending an SD/SDIO STOP command.†
7. Software must check for host timeout conditions in the rintsts register:†

    - Receive FIFO buffer data request†
    - Data starvation from host—the host is not reading from the FIFO buffer fast enough to keep up with data from the card. To correct this condition, software must perform the following steps:†

        - Read the fifo_count field of the status register†
        - Read the corresponding amount of data out of the FIFO buffer†

    In both cases, the software must read data from the FIFO buffer and make space in the FIFO buffer for receiving more data.†
8. When a DTO interrupt is received, the software must read the remaining data from the FIFO buffer.†

cmd Register Settings for Single-Block and Multiple-Block Reads[†]

Table 14-19: cmd Register Settings for Single-Block and Multiple-Block Reads (Default)

Parameter	Value	Comment
`start_cmd`	1	This bit resets itself to 0 after the command is committed.
`use_hold_reg`	1 or 0	Choose the value based on speed mode used.
`update_clk_regs_only`	0	Does not need to update clock parameters
`data_expected`	1	Data command
`card_number`	1	For one card
`transfer_mode`	0	Block transfer

Parameter	Value	Comment
`send_initialization`	0	1 for a card reset command such as the SD/SDIO GO_IDLE_STATE command 0 otherwise
`stop_abort_cmd`	0	1 for a command to stop data transfer such as the SD/SDIO STOP_TRANSMISSION command 0 otherwise
`send_auto_stop`	0 or 1	Refer to *Auto Stop* for information about how to set this parameter.
`read_write`	0	Read from card
`response_length`	0	1 for R2 (long) response 0 for short response
`response_expect`	1 or 0	0 for commands with no response, such as SD/SDIO GO_IDLE_STATE, SET_DSR, and GO_INACTIVE_STATE. 1 otherwise

Table 14-20: cmd Register Settings for Single-Block and Multiple-Block Reads (User Selectable)

Parameter	Value	Comment
`wait_prvdata_complete`	1 or 0	0 - sends command to CIU immediately 1 - sends command after previous data transfer ends
`check_response_crc`	1 or 0	0 - Controller must not check response CRC 1 - Controller must check responce CRC
`cmd_index`	Command Index	Set this parameter to the command number. For example, set to 17 or 18 for SD/SDIO READ_SINGLE_BLOCK (CMS17) or READ_MULTIPLE_BLOCK (CMD18)

Related Information

Auto-Stop on page 14-28
Refer to this table for information about setting the `send_auto_stop` parameter.

Single-Block or Multiple-Block Write

The following steps comprise a single-block or multiple-block write:

1. Write the data size in bytes to the bytcnt register. For a multi-block write, bytcnt must be a multiple of the block size.†
2. Write the block size in bytes to the blksiz register. The controller sends data in blocks of size blksiz each.†
3. Write the cmdarg register with the data address to which data must be written.†
4. Write data into the FIFO buffer. For best performance, the host software should write data continuously until the FIFO buffer is full.†
5. Write the cmd register with the parameters listed in *cmd Register Settings for Single-Block and Multiple-Block Write*. For SD and MMC cards, use the SD/SDIO WRITE_BLOCK (CMD24) command for a single-block write and the WRITE_MULTIPLE_BLOCK (CMD25) command for a multiple-block writes. For SDIO cards, use the IO_RW_EXTENDED command for both single-block and multiple-block transfers.†

   After writing to the cmd register, the controller starts executing a command if there is no other command already being processed. When the command is sent to the bus, a Command Done interrupt is generated.†
6. Software must check for data error interrupts; that is, for dcrc, bds, and ebe bits of the rintsts register. If required, software can terminate the data transfer early by sending the SD/SDIO STOP command.†
7. Software must check for host timeout conditions in the rintsts register: †

   - Transmit FIFO buffer data request.†
   - Data starvation by the host—the controller wrote data to the card faster than the host could supply the data.†

   In both cases, the software must write data into the FIFO buffer.†

   There are two types of transfers: open-ended and fixed length.†

   - Open-ended transfers—For an open-ended block transfer, the byte count is 0. At the end of the data transfer, software must send the STOP_TRANSMISSION command (CMD12).†
   - Fixed-length transfers—The byte count is nonzero. You must already have written the number of bytes to the bytcnt register. The controller issues the STOP command for you if you set the send_auto_stop bit of the cmd register to 1. After completion of a transfer of a given number of bytes, the controller sends the STOP command. Completion of the AUTO_STOP command is reflected by the Auto Command Done interrupt. A response to the AUTO_STOP command is written to the resp1 register. If software does not set the send_auto_stop bit in the cmd register to 1, software must issue the STOP command just like in the open-ended case.†

When the dto bit of the rintsts register is set, the data command is complete.†

cmd Register Settings for Single-Block and Multiple-Block Write

Table 14-21: cmd Register Settings for Single-Block and Multiple-Block Write (Default)†

Parameter	Value	Comment
start_cmd	1	This bit resets itself to 0 after the command is committed (accepted by the BIU).
use_hold_reg	1 or 0	Choose the value based on speed mode used.
update_clk_regs_only	0	Does not need to update clock parameters

Parameter	Value	Comment
`data_expected`	1	Data command
`card_number`	1	For one card
`transfer_mode`	0	Block transfer
`send_initialization`	0	Can be 1, but only for card reset commands such as SD/SDIO GO_IDLE_STATE
`stop_abort_cmd`	0	Can be 1 for commands to stop data transfer such as SD/SDIO STOP_TRANSMISSION
`send_auto_stop`	0 or 1	Refer to *Auto Stop* for information about how to set this parameter.
`read_write`	1	Write to card
`response_length`	0	Can be 1 for R2 (long) responses
`response_expect`	1	Can be 0 for commands with no response. For example, SD/SDIO GO_IDLE_STATE, SET_DSR, GO_INACTIVE_STATE etc.

Table 14-22: cmd Register Settings for Single-Block and Multiple-Block Write (User Selectable)†

Parameter	Value	Comment
`wait_prvdata_complete`	1	0—Sends command to the CIU immediately 1—Sends command after previous data transfer ends
`check_response_crc`	1	0—Controller must not check response CRC 1—Controller must check response CRC
`cmd_index`	Command Index	Set this parameter to the command number. For example, set to 24 for SD/SDIO WRITE_BLOCK (CMD24) or 25 for WRITE_MULTIPLE_BLOCK (CMD25).

Related Information

Auto-Stop on page 14-28
Refer to this table for information about setting the `send_auto_stop` parameter.

Stream Read and Write

In a stream transfer, if the byte count is equal to 0, the software must also send the SD/SDIO STOP command. If the byte count is not 0, when a given number of bytes completes a transfer, the controller sends the STOP command automatically. Completion of this AUTO_STOP command is reflected by the

Auto_command_done interrupt. A response to an AUTO_STOP command is written to the `resp1` register. A stream transfer is allowed only for card interfaces with a 1-bit data bus.†

A stream read requires the same steps as the block read described in *Single-Block or Multiple-Block Read*, except for the following bits in the `cmd` register:†

- `transfer_mode` = 0x1 (for stream transfer)†
- `cmd_index` = 20 (SD/SDIO CMD20)†

A stream write requires the same steps as the block write mentioned in *Single-Block or Multiple-Block Write*, except for the following bits in the `cmd` register:†

- `transfer_mode` = 0x1 (for stream transfer)†
- `cmd_index` = 11 (SD/SDIO CMD11)†

Related Information

- **Single-Block or Multiple-Block Read** on page 14-45
  Refer to this section for more information about a stream read.
- **Single-Block or Multiple-Block Write** on page 14-48
  Refer to this section for more information about a stream write.

Packed Commands

To reduce overhead, read and write commands can be packed in groups of commands—either all read or all write—that transfer the data for all commands in the group in one transfer on the bus. Use the SD/SDIO SET_BLOCK_COUNT (CMD23) command to state ahead of time how many blocks will be transferred. Then issue a single READ_MULTIPLE_BLOCK or WRITE_MULTIPLE_BLOCK command to read or write multiple blocks.†

- SET_BLOCK_COUNT—set block count (number of blocks transferred using the READ_MULTIPLE_BLOCK or WRITE_MULTIPLE_BLOCK command) †
- READ_MULTIPLE_BLOCK—multiple-block read command †
- WRITE_MULTIPLE_BLOCK—multiple-block write command†

Packed commands are organized in packets by the application software and are transparent to the controller.†

Related Information

www.jedec.org
For more information about packed commands, refer to JEDEC Standard No. 84-A441, available on the JEDEC website.

Transfer Stop and Abort Commands

This section describes stop and abort commands. The SD/SDIO STOP_TRANSMISSION command can terminate a data transfer between a memory card and the controller. The ABORT command can terminate an I/O data transfer for only an SDIO card. †

STOP_TRANSMISSION (CMD12)

The host can send the STOP_TRANSMISSION (CMD12) command on the CMD pin at any time while a data transfer is in progress. Perform the following steps to send the STOP_TRANSMISSION command to the SD/SDIO card device:†

1. Set the `wait_prvdata_complete` bit of the `cmd` register to 0.†
2. Set the `stop_abort_cmd` in the `cmd` register to 1, which ensures that the CIU stops.†

The STOP_TRANSMISSION command is a non-data transfer command.†

Related Information

Non-Data Transfer Commands on page 14-42
Refer to this section for information on the STOP_TRANSMISSION command.

ABORT

The ABORT command can only be used with SDIO cards. To abort the function that is transferring data, program the ABORT function number in the ASx[2:0] bits at address 0x06 of the card common control register (CCCR) in the card device, using the IO_RW_DIRECT (CMD52) command. The CCCR is located at the base of the card space 0x00 – 0xFF.†

Note: The ABORT command is a non-data transfer command.†

Related Information

Non-Data Transfer Commands on page 14-42
Refer to this section for information on the ABORT command.

Sending the ABORT Command

Perform the following steps to send the ABORT command to the SDIO card device:†

1. Set the `cmdarg` register to include the appropriate command argument parameters listed in *cmdarg Register Settings for SD/SDIO ABORT Command*.†
2. Send the IO_RW_DIRECT command by setting the following fields of the `cmd` register:†
   - Set the command index to 0x52 (IO_RW_DIRECT).†
   - Set the `stop_abort_cmd` bit of the `cmd` register to 1 to inform the controller that the host aborted the data transfer.†
   - Set the `wait_prvdata_complete` bit of the `cmd` register to 0.†
3. Wait for the `cmd` bit in the `rintsts` register to change to 1.†
4. Read the response to the IO_RW_DIRECT command (R5) in the response registers for any errors.†

For more information about response values, refer to the Physical Layer Simplified Specification, Version 3.01, available on the SD Association website.

Related Information

www.sdcard.org
To learn more about how SD technology works, visit the SD Association website.

cmdarg Register Settings for SD/SDIO ABORT Command†

Table 14-23: cmdarg Register Settings for SD/SDIO ABORT Command

Bits	Contents	Value
31	R/W flag	1
30:28	Function number	0, for access to the CCCR in the card device

Bits	Contents	Value
27	RAW flag	1, if needed to read after write
26	Don't care	-
25:9	Register address	0x06
8	Don't care	-
7:0	Write data	Function number to abort

Internal DMA Controller Operations

For better performance, you can use the internal DMA controller to transfer data between the host and the controller. This section describes the internal DMA controller’s initialization process, and transmission sequence, and reception sequence.

Internal DMA Controller Initialization

To initialize the internal DMA controller, perform the following steps:†

1. Set the required `bmod` register bits: †
   - If the internal DMA controller enable bit (`de`) of the `bmod` register is set to 0 during the middle of a DMA transfer, the change has no effect. Disabling only takes effect for a new data transfer command.†
   - Issuing a software reset immediately terminates the transfer. Prior to issuing a software reset, Altera recommends the host reset the DMA interface by setting the `dma_reset` bit of the `ctrl` register to 1.†
   - The `pbl` field of the `bmod` register is read-only and a direct reflection of the contents of the DMA multiple transaction size field (`dw_dma_multiple_transaction_size`) in the `fifoth` register.†
   - The `fb` bit of the `bmod` register has to be set appropriately for system performance.†
2. Write to the `idinten` register to mask unnecessary interrupt causes according to the following guidelines:†
   - When a Descriptor Unavailable interrupt is asserted, the software needs to form the descriptor, appropriately set its own bit, and then write to the poll demand register (`pldmnd`) for the internal DMA controller to re-fetch the descriptor.†
   - It is always appropriate for the software to enable abnormal interrupts because any errors related to the transfer are reported to the software.†
3. Populate either a transmit or receive descriptor list in memory. Then write the base address of the first descriptor in the list to the internal DMA controller’s descriptor list base address register (`dbaddr`). The DMA controller then proceeds to load the descriptor list from memory. *Internal DMA Controller Transmission Sequences* and *Internal DMA Controller Reception Sequences* describe this step in detail. †

Related Information

- **Internal DMA Controller Transmission Sequences** on page 14-54
  Refer to this section for information about the Internal DMA Controller Transmission Sequences.
- **Internal DMA Controller Reception Sequences** on page 14-54
  Refer to this section for information about the Internal DMA Controller Reception Sequences.

Internal DMA Controller Transmission Sequences

To use the internal DMA controller to transmit data, perform the following steps:

1. The host sets up the Descriptor fields (DES0—DES3) for transmission and sets the OWN bit (DES0[31]) to 1. The host also loads the data buffer in system memory with the data to be written to the SD card.†
2. The host writes the appropriate write data command (SD/SDIO WRITE_BLOCK or WRITE_MULTIPLE_BLOCK) to the `cmd` register. The internal DMA controller determines that a write data transfer needs to be performed.†
3. The host sets the required transmit threshold level in the `tx_wmark` field in the `fifoth` register.†
4. The internal DMA controller engine fetches the descriptor and checks the OWN bit. If the OWN bit is set to 0, the host owns the descriptor. In this case, the internal DMA controller enters the suspend state and asserts the Descriptor Unable interrupt. The host then needs to set the descriptor OWN bit to 1 and release the DMA controller by writing any value to the `pldmnd` register.†
5. The host must write the descriptor base address to the `dbaddr` register.†
6. The internal DMA controller waits for the Command Done (`CD`) bit in the `rintsts` register to be set to 1, with no errors from the BIU. This condition indicates that a transfer can be done.†
7. The internal DMA controller engine waits for a DMA interface request from BIU. The BIU divides each transfer into smaller chunks. Each chunk is an internal request to the DMA. This request is generated based on the transmit threshold value.†
8. The internal DMA controller fetches the transmit data from the data buffer in the system memory and transfers the data to the FIFO buffer in preparation for transmission to the card.†
9. When data spans across multiple descriptors, the internal DMA controller fetches the next descriptor and continues with its operation with the next descriptor. The Last Descriptor bit in the descriptor DES0 field indicates whether the data spans multiple descriptors or not.†
10. When data transmission is complete, status information is updated in the `idsts` register by setting the `ti` bit to 1, if enabled. Also, the OWN bit is set to 0 by the DMA controller by updating the DES0 field of the descriptor.†

Internal DMA Controller Reception Sequences

To use the internal DMA controller to receive data, perform the following steps:

1. The host sets up the descriptor fields (DES0—DES3) for reception, sets the OWN (DES0 [31]) to 1.†
2. The host writes the read data command to the `cmd` register in BIU. The internal DMA controller determines that a read data transfer needs to be performed.†
3. The host sets the required receive threshold level in the `rx_wmark` field in the `fifoth` register.†
4. The internal DMA controller engine fetches the descriptor and checks the OWN bit. If the OWN bit is set to 0, the host owns the descriptor. In this case, the internal DMA controller enters suspend state and asserts the Descriptor Unable interrupt. The host then needs to set the descriptor OWN bit to 1 and release the DMA controller by writing any value to the `pldmnd` register.†
5. The host must write the descriptor base address to the `dbaddr` register.†
6. The internal DMA controller waits for the `CD` bit in the `rintsts` register to be set to 1, with no errors from the BIU. This condition indicates that a transfer can be done.†
7. The internal DMA controller engine waits for a DMA interface request from the BIU. The BIU divides each transfer into smaller chunks. Each chunk is an internal request to the DMA. This request is generated based on the receive threshold value.†

8. The internal DMA controller fetches the data from the FIFO buffer and transfers the data to system memory.†
9. When data spans across multiple descriptors, the internal DMA controller fetches the next descriptor and continues with its operation with the next descriptor. The Last Descriptor bit in the descriptor indicates whether the data spans multiple descriptors or not.†
10. When data reception is complete, status information is updated in the `idsts` register by setting the `ri` bit to 1, if enabled. Also, the OWN bit is set to 0 by the DMA controller by updating the DES0 field of the descriptor.†

Commands for SDIO Card Devices

This section describes the commands to temporarily halt the transfers between the controller and SDIO card device.

Suspend and Resume Sequence

For SDIO cards, a data transfer between an I/O function and the controller can be temporarily halted using the SUSPEND command. This capability might be required to perform a high-priority data transfer with another function. When desired, the suspended data transfer can be resumed using the RESUME command.†

The SUSPEND and RESUME operations are implemented by writing to the appropriate bits in the CCCR (Function 0) of the SDIO card. To read from or write to the CCCR, use the controller's IO_RW_DIRECT command.†

Suspend

To suspend data transfer, perform the following steps:†

1. Check if the SDIO card supports the SUSPEND/RESUME protocol. This can be done through the SBS bit in the CCCR at offset 0x08 of the card.†
2. Check if the data transfer for the required function number is in process. The function number that is currently active is reflected in the function select bits (FSx) of the CCCR, bits 3:0 at offset 0x0D of the card.†

   Note: If the bus status bit (BS), bit 0 at address 0xC, is 1, only the function number given by the FSx bits is valid.†
3. To suspend the transfer, set the bus release bit (BR), bit 2 at address 0xC, to 1.†
4. Poll the BR and BS bits of the CCCR at offset 0x0C of the card until they are set to 0. The BS bit is 1 when the currently-selected function is using the data bus. The BR bit remains 1 until the bus release is complete. When the BR and BS bits are 0, the data transfer from the selected function is suspended.†
5. During a read-data transfer, the controller can be waiting for the data from the card. If the data transfer is a read from a card, the controller must be informed after the successful completion of the SUSPEND command. The controller then resets the data state machine and comes out of the wait state. To accomplish this, set the abort read data bit (`abort_read_data`) in the `ctrl` register to 1.†
6. Wait for data completion, by polling until the `dto` bit is set to 1 in the `rintsts` register. To determine the number of pending bytes to transfer, read the transferred CIU card byte count (`tcbcnt`) register of the controller. Subtract this value from the total transfer size. You use this number to resume the transfer properly.†

Resume

To resume the data transfer, perform the following steps:†

1. Check that the card is not in a transfer state, which confirms that the bus is free for data transfer.†
2. If the card is in a disconnect state, select it using the SD/SDIO SELECT/DESELECT_CARD command. The card status can be retrieved in response to an IO_RW_DIRECT or IO_RW_EXTENDED command.†
3. Check that a function to be resumed is ready for data transfer. Determine this state by reading the corresponding RF<*n*> flag in CCCR at offset 0x0F of the card. If RF<*n*> = 1, the function is ready for data transfer.†

   Note: For detailed information about the RF<*n*> flags, refer to SDIO Simplified Specification Version 2.00, available on the SD Association website.†
4. To resume transfer, use the IO_RW_DIRECT command to write the function number at the FSx bits in the CCCR, bits 3:0 at offset 0x0D of the card. Form the command argument for the IO_RW_DIRECT command and write it to the `cmdarg` register. Bit values are listed in the following table.†

Table 14-24: cmdarg Bit Values for RESUME Command†

Bits	Content	Value
31	R/W flag	1
30:28	Function number	0, for CCCR access
27	RAW flag	1, read after write
26	Don't care	-
25:9	Register address	0x0D
8	Don't care	-
7:0	Write data	Function number that is to be resumed

5. Write the block size value to the `blksiz` register. Data is transferred in units of this block size.†
6. Write the byte count value to the `bytcnt` register. Specify the total size of the data that is the remaining bytes to be transferred. It is the responsibility of the software to handle the data.†

   To determine the number of pending bytes to transfer, read the transferred CIU card byte count register (`tcbcnt`). Subtract this value from the total transfer size to calculate the number of remaining bytes to transfer.†
7. Write to the `cmd` register similar to a block transfer operation. When the `cmd` register is written, the command is sent and the function resumes data transfer. For more information, refer to *Single-Block or Multiple-Block Read* and *Single-Block or Multiple-Block Write*.†
8. Read the resume data flag (DF) of the SDIO card device. Interpret the DF flag as follows:†

- DF=1—The function has data for the transfer and begins a data transfer as soon as the function or memory is resumed.†
- DF=0—The function has no data for the transfer. If the data transfer is a read, the controller waits for data. After the data timeout period, it issues a data timeout error.†

  Refer to this section for more information about writing to the `cmd` register.

Read-Wait Sequence

Read_wait is used with SDIO cards only. It temporarily stalls the data transfer, either from functions or memory, and allows the host to send commands to any function within the SDIO card device. The host can stall this transfer for as long as required. The controller provides the facility to signal this stall transfer to the card.†

Signalling a Stall

To signal the stall, perform the following steps:†

1. Check if the card supports the read_wait facility by reading the SDIO card's SRW bit, bit 2 at offset 0x8 in the CCCR.†
2. If this bit is 1, all functions in the card support the read_wait facility. Use the SD/SDIO IO_RW_DIRECT command to read this bit.†
3. If the card supports the `read_wait` signal, assert it by setting the read wait bit (`read_wait`) in the `ctrl` register to 1.†
4. Reset the `read_wait` bit to 0 in the `ctrl` register.†

CE-ATA Data Transfer Commands

This section describes CE-ATA data transfer commands.

Related Information

Data Transfer Commands on page 14-44
Refer to this section for information about the basic settings and interrupts generated for different conditions.

Reset and Card Device Discovery Overview

Before starting any CE-ATA operations, the host must perform a MMC reset and initialization procedure. The host and card device must negotiate the MMC transfer (MMC TRAN) state before the card enters the MMC TRAN state.†

The host must follow the existing MMC discovery procedure to negotiate the MMC TRAN state. After completing normal MMC reset and initialization procedures, the host must query the initial ATA task file values using the RW_REG or CMD39 command.†

By default, the MMC block size is 512 bytes—indicated by bits 1:0 of the srcControl register inside the CE-ATA card device. The host can negotiate the use of a 1 KB or 4 KB MMC block sizes. The card indicates MMC block sizes that it can support through the srcCapabilities register in the MMC; the host reads this register to negotiate the MMC block size. Negotiation is complete when the host controller writes the MMC block size into the srcControl register bits 1:0 of the card.†

Related Information

www.jedec.org
For information about the (MMC TRAN) state, MMC reset and initialization, refer to JEDEC Standard No. 84-A441, available on the JEDEC website.

ATA Task File Transfer Overview

ATA task file registers are mapped to addresses 0x00h through 0x10h in the MMC register space. The RW_REG command is used to issue the ATA command, and the ATA task file is transmitted in a single RW_REG MMC command sequence.†

The host software stack must write the task file image to the FIFO buffer before setting the `cmdarg` and `cmd` registers in the controller. The host processor then writes the address and byte count to the `cmdarg` register before setting the `cmd` register bits.†

For the RW_REG command, there is no CCS from the CE-ATA card device. †

ATA Task File Transfer Using the RW_MULTIPLE_REGISTER (RW_REG) Command

This command involves data transfer between the CE-ATA card device and the controller. To send a data command, the controller needs a command argument, total data size, and block size. Software receives or sends data through the FIFO buffer.†

Implementing ATA Task File Transfer

To implement an ATA task file transfer (read or write), perform the following steps:†

1. Write the data size in bytes to the `bytcnt` register. `bytcnt` must equal the block size, because the controller expects a single block transfer.†
2. Write the block size in bytes to the `blksiz` register.†
3. Write the `cmdarg` register with the beginning register address.†

You must set the `cmdarg`, `cmd`, `blksiz`, and `bytcnt` registers according to the tables in *Register Settings for ATA Task File Transfer*.†

Related Information

Register Settings for ATA Task File Transfer on page 14-58
Refer to this table for information on how to set these registers.

Register Settings for ATA Task File Transfer

Table 14-25: cmdarg Register Settings for ATA Task File Transfer†

Bit	Value	Comment
31	1 or 0	Set to 0 for read operation or set to 1 for write operation
30:24	0	Reserved (bits set to 0 by host processor)
23:18	0	Starting register address for read or write (DWORD aligned)
17:16	0	Register address (DWORD aligned)

Bit	Value	Comment
15:8	0	Reserved (bits set to 0 by host processor)
7:2	16	Number of bytes to read or write (integral number of DWORD)
1:0	0	Byte count in integral number of DWORD

Table 14-26: cmd Register Settings for ATA Task File Transfer†

Bit	Value	Comment
`start_cmd`	1	
`ccs_expected`	0	CCS is not expected
`read_ceata_device`	0 or 1	Set to 1 if RW_BLK or RW_REG read
`update_clk_regs_only`	0	No clock parameters update command
`card_num`	0	
`send_initialization`	0	No initialization sequence
`stop_abort_cmd`	0	
`send_auto_stop`	0	
`transfer_mode`	0	Block transfer mode. Block size and byte count must match number of bytes to read or write
`read_write`	1 or 0	1 for write and 0 for read
`data_expected`	1	Data is expected
`response_length`	0	
`response_expect`	1	
`cmd_index`	Command index	Set this parameter to the command number. For example, set to 24 for SD/SDIO WRITE_BLOCK (CMD24) or 25 for WRITE_MULTIPLE_BLOCK (CMD25).
`wait_prvdata_complete`	1	• 0 for send command immediately • 1 for send command after previous DTO interrupt
`check_response_crc`	1	• 0 for not checking response CRC • 1 for checking response CRC

Table 14-27: blksiz Register Settings for ATA Task File Transfer†

Bit	Value	Comment
31:16	0	Reserved bits set to 0
15:0 (`block_size`)	16	For accessing entire task file (16, 8-bit registers). Block size of 16 bytes

Table 14-28: bytcnt Register Settings for ATA Task File Transfer

Bit	Value	Comment
31:0	16	For accessing entire task file (16, 8-bit registers). Byte count value of 16 is used with the block size set to 16.

ATA Payload Transfer Using the RW_MULTIPLE_BLOCK (RW_BLK) Command

This command involves data transfer between the CE-ATA card device and the controller. To send a data command, the controller needs a command argument, total data size, and block size. Software receives or sends data through the FIFO buffer. †

Implementing ATA Payload Transfer

To implement an ATA payload transfer (read or write), perform the following steps:†

1. Write the data size in bytes to the `bytcnt` register.†
2. Write the block size in bytes to the `blksiz` register. The controller expects a single/multiple block transfer.†
3. Write to the `cmdarg` register to indicate the data unit count.†

Register Settings for ATA Payload Transfer

You must set the `cmdarg`, `cmd`, `blksiz`, and `bytcnt` registers according to the following tables.†

Table 14-29: cmdarg Register Settings for ATA Payload Transfer†

Bits	Value	Comment
31	1 or 0	Set to 0 for read operation or set to 1 for write operation
30:24	0	Reserved (bits set to 0 by host processor)
23:16	0	Reserved (bits set to 0 by host processor)
15:8	Data count	Data Count Unit [15:8]
7:0	Data count	Data Count Unit [7:0]

Table 14-30: cmd Register Settings for ATA Payload Transfer†

Bits	Value	Comment
start_cmd	1	-
ccs_expected	1	CCS is expected. Set to 1 for the RW_BLK command if interrupts are enabled in CE-ATA card device (the nIEN bit is set to 0 in the ATA control register)
read_ceata_device	0 or 1	Set to 1 for a RW_BLK or RW_REG read command
update_clk_regs_only	0	No clock parameters update command
card_num	0	-
send_initialization	0	No initialization sequence
stop_abort_cmd	0	-
send_auto_stop	0	-
transfer_mode	0	Block transfer mode. Byte count must be integer multiple of 4kB. Block size can be 512, 1k or 4k bytes
read_write	1 or 0	1 for write and 0 for read
data_expected	1	Data is expected
response_length	0	-
response_expect	1	-
cmd_index	Command index	Set this parameter to the command number. For example, set to 24 for SD/SDIO WRITE_BLOCK (CMD24) or 25 for WRITE_MULTIPLE_BLOCK (CMD25).
wait_prvdata_complete	1	• 0 for send command immediately • 1 for send command after previous DTO interrupt
check_response_crc	1	• 0 for not checking response CRC • 1 for checking response CRC

Table 14-31: blksiz Register Settings for ATA Payload Transfer†

Bits	Value	Comment
31:16	0	Reserved bits set to 0
15:0 (block_size)	512, 1024 or 4096	MMC block size can be 512, 1024 or 4096 bytes as negotiated by host

Table 14-32: bytcnt Register Settings for ATA Payload Transfer

Bits	Value	Comment
31:0	<n>*block_size	Byte count must be an integer multiple of the block size. For ATA media access commands, byte count must be a multiple of 4 KB. (<*n*>*block_size = <*x*>*4 KB, where <*n*> and <*x*> are integers)

CE-ATA CCS

This section describes disabling the CCS, recovery after CCS timeout, and recovery after I/O read transmission delay (N_{ACIO}) timeout. †

Disabling the CCS

While waiting for the CCS for an outstanding RW_BLK command, the host can disable the CCS by sending a CCSD command:†

- Send a CCSD command—the controller sends the CCSD command to the CE-ATA card device if the send_ccsd bit is set to 1 in the ctrl register of the controller. This bit can be set only after a response is received for the RW_BLK command.†
- Send an internal stop command—send an internally-generated SD/SDIO STOP_TRANSMISSION (CMD12) command after sending the CCSD pattern. If the send_auto_stop_ccsd bit of the ctrl register is also set to 1 when the controller is set to send the CCSD pattern, the controller sends the internally-generated STOP command to the CMD pin. After sending the STOP command, the controller sets the acd bit in the rintsts register to 1.†

Recovery after CCS Timeout

If a timeout occurs while waiting for the CCS, the host needs to send the CCSD command followed by a STOP command to abort the pending ATA command. The host can set up the controller to send an internally-generated STOP command after sending the CCSD pattern:†

- Send CCSD command—set the `send_ccsd` bit in the `ctrl` register to 1.†
- Send external STOP command—terminate the data transfer between the CE-ATA card device and the controller. For more information about sending the STOP command, refer to *Transfer Stop and Abort Commands*.†
- Send internal STOP command—set the `send_auto_stop_ccsd` bit in the `ctrl` register to 1, which tells the controller to send the internally-generated STOP command. After sending the STOP command, the controller sets the `acd` bit in the `rintsts` register to 1. The `send_auto_stop_ccsd` bit must be set to 1 along with setting the `send_ccsd` bit.†

Related Information

Transfer Stop and Abort Commands on page 14-51
Refer to this section for more information about sending the STOP command.

Recovery after I/O Read Transmission Delay (N_{ACIO}) Timeout

If the I/O read transmission delay (N_{ACIO}) timeout occurs for the CE-ATA card device, perform one of the following steps to recover from the timeout:†

- If the CCS is expected from the CE-ATA card device (that is, the `ccs_expected` bit is set to 1 in the `cmd` register), follow the steps in *Recovery after CCS Timeout*.†
- If the CCS is not expected from the CE-ATA card device, perform the following steps: †

  1. Send an external STOP command. †
  2. Terminate the data transfer between the controller and CE-ATA card device. †

Related Information

Recovery after CCS Timeout on page 14-62
For more information about what steps to take if the CCS is expected from the CE-ATA card device.

Reduced ATA Command Set

It is necessary for the CE-ATA card device to support the reduced ATA command subset. This section describes the reduced command set.†

The IDENTIFY DEVICE Command

The IDENTIFY DEVICE command returns a 512-byte data structure to the host that describes device-specific information and capabilities. The host issues the IDENTIFY DEVICE command only if the MMC block size is set to 512 bytes. Any other MMC block size has indeterminate results.†

The host issues a RW_REG command for the ATA command, and the data is retrieved with the RW_BLK command.†

The host controller uses the following settings while sending a RW_REG command for the IDENTIFY DEVICE ATA command. The following list shows the primary bit settings:†

- `cmd` register setting: `data_expected` bit set to 0†
- `cmdarg` register settings: †
  - Bit [31] set to 0†
  - Bits [7:2] set to 128 †
  - All other bits set to 0†
- Task file settings: †
  - Command field of the ATA task file set to 0xEC†
  - Reserved fields of the task file set to 0†
- `bytcnt` register and `block_size` field of the `blksiz` register: set to 16†

The host controller uses the following settings for data retrieval (RW_BLK command):†

- `cmd` register settings:†
  - `ccs_expected` set to 1†
  - `data_expected` set to 1†
- `cmdarg` register settings: †
  - Bit [31] set to 0 (read operation) †
  - Bits [15:0] set to 1 (data unit count = 1)†
  - All other bits set to 0†
- `bytcnt` register and `block_size` field of the `blksiz` register: set to 512†

The READ DMA EXT Command

The READ DMA EXT command reads a number of logical blocks of data from the card device using the Data-In data transfer protocol. The host uses a RW_REG command to issue the ATA command and the RW_BLK command for the data transfer.†

The WRITE DMA EXT Command

The WRITE DMA EXT command writes a number of logical blocks of data to the card device using the Data-Out data transfer protocol. The host uses a RW_REG command to issue the ATA command and the RW_BLK command for the data transfer.†

The STANDBY IMMEDIATE Command

This ATA command causes the card device to immediately enter the most aggressive power management mode that still retains internal device context. No data transfer (RW_BLK) is expected for this command.†

For card devices that do not provide a power savings mode, the STANDBY IMMEDIATE command returns a successful status indication. The host issues a RW_REG command for the ATA command, and the status is retrieved with the SD/SDIO CMD39 or RW_REG command. Only the status field of the ATA task file contains the success status; there is no error status.†

The host controller uses the following settings while sending the RW_REG command for the STANDBY IMMEDIATE ATA command: †

- `cmd` register setting: `data_expected` bit set to 0†
- `cmdarg` register settings: †
  - Bit [31] set to 1 †
  - Bits [7:2] set to 4 †
  - All other bits set to 0 †
- Task file settings: †
  - Command field of the ATA task file set to 0xE0†
  - Reserved fields of the task file set to 0†
- `bytcnt` register and `block_size` field of the `blksiz` register: set to 16 †

The FLUSH CACHE EXT Command

For card devices that buffer/cache written data, the FLUSH CACHE EXT command ensures that buffered data is written to the card media. For cards that do not buffer written data, the FLUSH CACHE EXT command returns a success status. No data transfer (RW_BLK) is expected for this ATA command. †

The host issues a RW_REG command for the ATA command, and the status is retrieved with the SD/SDIO CMD39 or RW_REG command. There can be error status for this ATA command, in which case fields other than the status field of the ATA task file are valid.†

The host controller uses the following settings while sending the RW_REG command for the STANDBY IMMEDIATE ATA command:†

- cmd register setting: data_expected bit set to 0 †
- cmdarg register settings: †
    - Bit [31] set to 1 †
    - Bits [7:2] set to 4†
    - All other bits set to 0†
- Task file settings: †
    - Command field of the ATA task file set to 0xEA †
    - Reserved fields of the task file set to 0†
- bytcnt register and block_size field of the blksiz register: set to 16 †

Card Read Threshold

When an application needs to perform a single or multiple block read command, the application must set the cardthrctl register with the appropriate card read threshold size in the card read threshold field (cardrdthreshold) and set the cardrdthren bit to 1. This additional information specified in the controller ensures that the controller sends a read command only if there is space equal to the card read threshold available in the RX FIFO buffer. This in turn ensures that the card clock is not stopped in the middle a block of data being transmitted from the card. Set the card read threshold to the block size of the transfer to guarantee there is a minimum of one block size of space in the RX FIFO buffer before the controller enables the card clock. †

The card read threshold is required when the round trip delay is greater than half of sdmmc_clk_divided.†

Table 14-33: Card Read Threshold Guidelines†

Bus Speed Modes	Round Trip Delay (Delay_R) [39]	Is Stopping of Card Clock Allowed?	Card Read Threshold Required?
SDR25	Delay_R > 0.5 * (sdmmc_clk/4)	No	Yes
	Delay_R < 0.5 * (sdmmc_clk/4)	Yes	No
SDR12	Delay_R > 0.5 * (sdmmc_clk/4)	No	Yes
	Delay_R < 0.5 * (sdmmc_clk/4)	Yes	No

Related Information

http://www.altera.com/literature/hb/cyclone-v/cv_51002.pdf

[39] Delay_R = Delay_O + tODLY + Delay_I †

Where: †

Delay_O = sdmmc_clk to sdmmc_cclk_out delay (including I/O pin delay) †

Delay_I = Input I/O pin delay + routing delay to the input register †

tODLY = sdmmc_cclk_out to card output delay (varies across card manufactures and speed modes) †

For the delay numbers needed for above calculation, refer to Arria 10 Datasheet. †

Recommended Usage Guidelines for Card Read Threshold

1. The `cardthrctl` register must be set before setting the `cmd` register for a data read command.†
2. The `cardthrctl` register must not be set while a data transfer command is in progress.†
3. The `cardrdthreshold` field of the `cardthrctl` register must be set to at the least the block size of a single or multiblock transfer. A `cardrdthreshold` field setting greater than or equal to the block size of the read transfer ensures that the card clock does not stop in the middle of a block of data.†
4. If the round trip delay is greater than half of the card clock period, card read threshold must be enabled and the card threshold must be set as per guideline 3 to guarantee that the card clock does not stop in the middle of a block of data.†
5. If the `cardrdthreshold` field is set to less than the block size of the transfer, the host must ensure that the receive FIFO buffer never overflows during the read transfer. Overflow can cause the card clock from the controller to stop. The controller is not able to guarantee that the card clock does not stop during a read transfer.†

Note: If the `cardrdthreshold` field of the `cardthrctl` register, and the `rx_wmark` and `dw_dma_multiple_transaction_size` fields of the `fifoth` register are set incorrectly, the card clock might stop indefinitely, with no interrupts generated by the controller.†

Card Read Threshold Programming Sequence

Most cards, such as SDHC or SDXC, support block sizes that are either specified in the card or are fixed to 512 bytes. For SDIO, MMC, and standard capacity SD cards that support partial block read (READ_BL_PARTIAL set to 1 in the CSD register of the card device), the block size is variable and can be chosen by the application.†

To use the card read threshold feature effectively and to guarantee that the card clock does not stop because of a FIFO Full condition in the middle of a block of data being read from the card, follow these steps:†

1. Choose a block size that is a multiple of four bytes.†
2. Enable card read threshold feature. The card read threshold can be enabled only if the block size for the given transfer is less than or equal to the total depth of the FIFO buffer:†

   (block size / 4) ≤ 1024†
3. Choose the card read threshold value: †
   - If (block size / 4) ≥ 512, choose `cardrdthreshold` such that:†
     - `cardrdthreshold` ≤ (block size / 4) in bytes†
   - If (block size / 4) < 512, choose `cardrdthreshold` such that:†
     - `cardrdthreshold` = (block size / 4) in bytes†
4. Set the `dw_dma_multiple_transaction_size` field in the `fifoth` register to the number of transfers that make up a DMA transaction. For example, size = 1 means 4 bytes are moved. The possible values for the size are 1, 4, 8, 16, 32, 64, 128, and 256 transfers. Select the size so that the value (block size / 4) is evenly divided by the size.†
5. Set the `rx_wmark` field in the `fifoth` register to the size – 1.†

For example, if your block size is 512 bytes, legal values of `dw_dma_multiple_transaction_size` and `rx_wmark` are listed in the following table.

Table 14-34: Legal Values of dw_dma_multiple_transaction_size and rx_wmark for Block Size = 512†

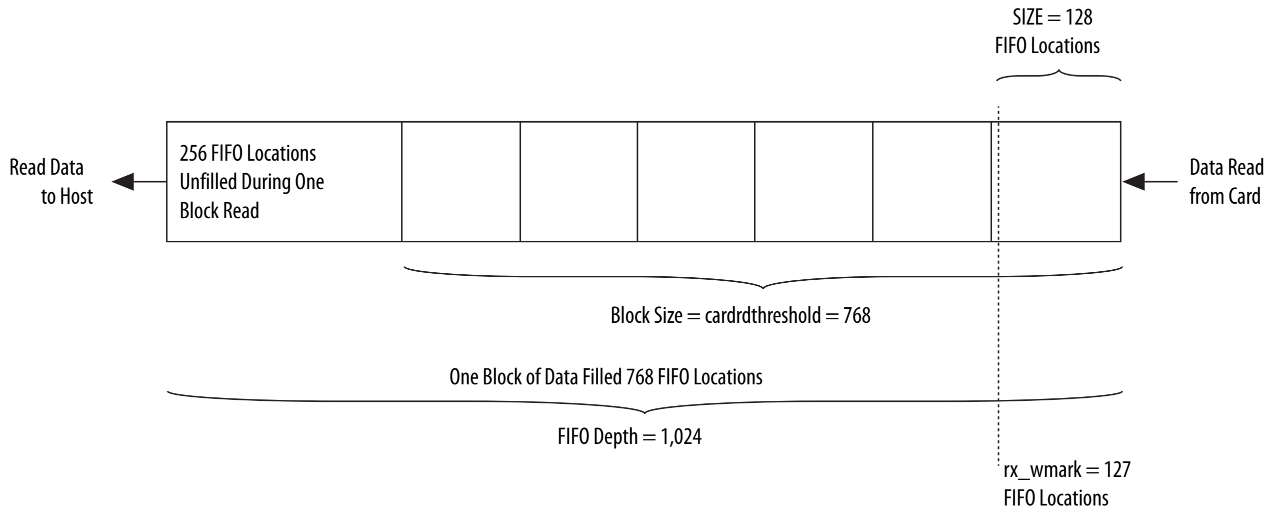
Block Size	dw_dma_multiple_transaction_size	rx_wmark
512	1	0
512	4	3
512	8	7
512	16	15
512	32	31
512	64	63
512	128	127

Card Read Threshold Programming Examples

This section shows examples of how to program the card read threshold.†

- Choose a block size that is a multiple of 4 (the number of bytes per FIFO location), and less than 4096 (1024 FIFO locations). For example, a block size of 3072 bytes is legal, because 3072 / 4 = 768 FIFO locations.†
- For DMA mode, choose the size so that block size is a multiple of the size. For example size = 128, where block size%size = 0.†
- Set the `rx_wmark` field = size – 1. For example, the `rx_wmark` field = 128 – 1 = 127.†
- Because block size > ½ FifoDepth, set the `cardrdthreshold` field to the block size. For example, the `cardrdthreshold` field = 3072 bytes.†

Figure 14-14: FIFO Buffer content when Card Read Threshold is set to 768†



Interrupt and Error Handling

This section describes how to use interrupts to handle errors. On power-on or reset, interrupts are disabled (the `int_enable` bit in the `ctrl` register is set to 0), and all the interrupts are masked (the `intmask` register default is 0). The controller error handling includes the following types of errors:

- Response and data timeout errors—For response time-outs, the host software can retry the command. For data time-outs, the controller has not received the data start bit from the card, so software can either retry the whole data transfer again or retry from a specified block onwards. By reading the contents of the `tcbcnt` register later, the software can decide how many bytes remain to be copied (read). †
- Response errors—Set to 1 when an error is received during response reception. If the response received is invalid, the software can retry the command. †
- Data errors—Set to 1 when a data receive error occurs. Examples of data receive errors: †
  - Data CRC†
  - Start bit not found †
  - End bit not found †

  These errors can be occur on any block. On receipt of an error, the software can issue an SD/SDIO STOP or SEND_IF_COND command, and retry the command for either the whole data or partial data.†
- Hardware locked error—Set to 1 when the controller cannot load a command issued by software. When software sets the `start_cmd` bit in the `cmd` register to 1, the controller tries to load the command. If the command buffer already contains a command, this error is raised, and the new command is discarded, requiring the software to reload the command.†
- FIFO buffer underrun/overrun error—If the FIFO buffer is full and software tries to write data to the FIFO buffer, an overrun error is set. Conversely, if the FIFO buffer is empty and the software tries to read data from the FIFO buffer, an underrun error is set. Before reading or writing data in the FIFO buffer, the software must read the FIFO buffer empty bit (`fifo_empty`) or FIFO buffer full bit (`fifo_full`) in the `status` register.†
- Data starvation by host timeout—This condition occurs when software does not service the FIFO buffer fast enough to keep up with the controller. Under this condition and when a read transfer is in process, the software must read data from the FIFO buffer, which creates space for further data reception. When a transmit operation is in process, the software must write data to fill the FIFO buffer so that the controller can write the data to the card.†
- CE-ATA errors†
- CRC error on command—If a CRC error is detected for a command, the CE-ATA card device does not send a response, and a response timeout is expected from the controller. The ATA layer is notified that an MMC transport layer error occurred.

- CRC error on command—If a CRC error is detected for a command, the CE-ATA card device does not send a response, and a response timeout is expected from the controller. The ATA layer is notified that an MMC transport layer error occurred.†
- Write operation—Any MMC transport layer error known to the card device causes an outstanding ATA command to be terminated. The ERR bits are set in the ATA status registers and the appropriate error code is sent to the Error Register (Error) on the ATA card device.†

  If the device interrupt bit of the CE-ATA card (the nIEN bit in the ATA control register) is set to 0, the CCS is sent to the host.†

  If the device interrupt bit is set to 1, the card device completes the entire data unit count if the host controller does not abort the ongoing transfer.†

  Note: During a multiple-block data transfer, if a negative CRC status is received from the card device, the data path signals a data CRC error to the BIU by setting the `dcrc` bit in the `rintsts` register to 1. It then continues further data transmission until all the bytes are transmitted.†
- Read operation—If MMC transport layer errors are detected by the host controller, the host completes the ATA command with an error status. The host controller can issue a CCSD command followed by a STOP_TRANSMISSION (CMD12) command to abort the read transfer. The host can also transfer the entire data unit count bytes without aborting the data transfer.†

Booting Operation for eMMC and MMC

This section describes how to set up the controller for eMMC and MMC boot operation.

Boot Operation by Holding Down the CMD Line

The controller can boot from MMC4.3, MMC4.4, and MMC4.41 cards by holding down the CMD line.

For information about this boot method, refer to the following specifications, available on the JEDEC website:

- JEDEC Standard No. 84-A441
- JEDEC Standard No. 84-A44
- JEDEC Standard No. JESD84-A43

Related Information

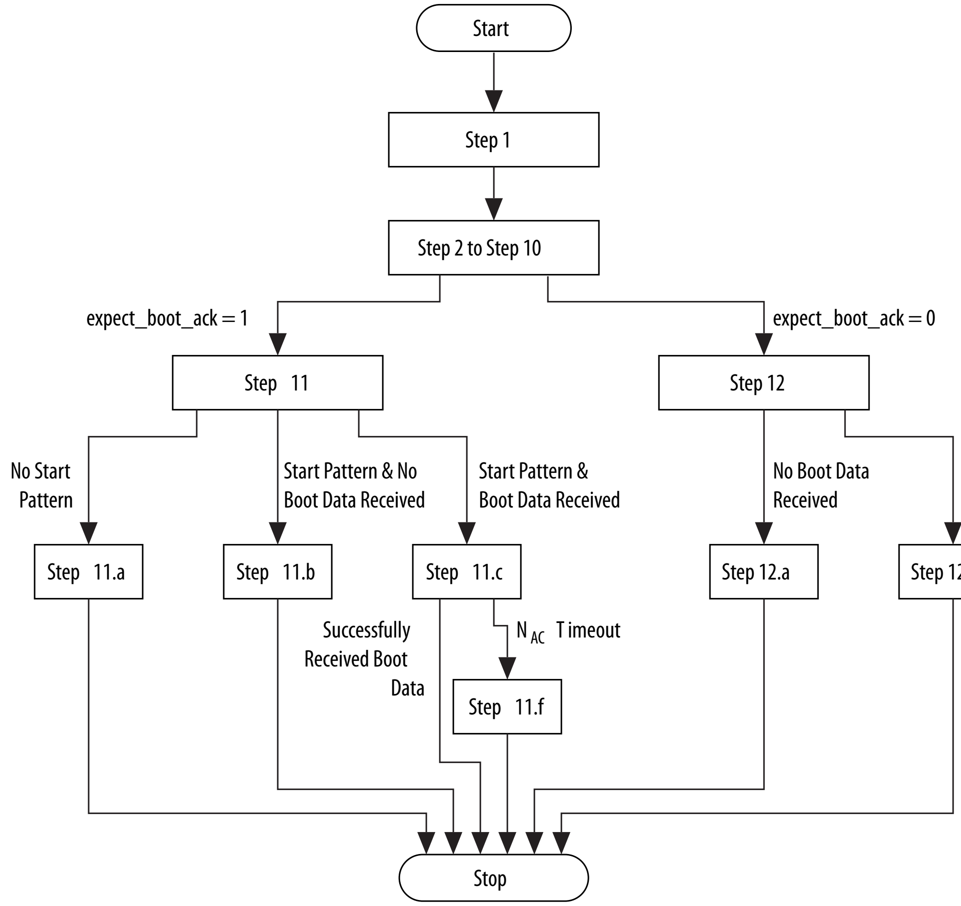
www.jedec.org

For more information about this boot method, refer to the following JEDEC Standards available on the JEDEC website: No. 84-A441, No. 84-A44, and No. JESD84-A43.

Boot Operation for eMMC Card Device

The following figure illustrates the steps to perform the boot process for eMMC card devices. The detailed steps are described following the flow chart.

Figure 14-15: Flow for eMMC Boot Operation†



1. The software driver performs the following checks: †
   - If the eMMC card device supports boot operation (the BOOT_PARTITION_ENABLE bit is set to 1 in the EXT_CSD register of the eMMC card).†
   - The BOOT_SIZE_MULT and BOOT_BUS_WIDTH values in the EXT_CSD register, to be used during the boot process.†
2. The software sets the following bits: †
   - Sets masks for interrupts, by setting the appropriate bits to 0 in the `intmask` register.†
   - Sets the global `int_enable` bit of the `ctrl` register to 1. Other bits in the `ctrl` register must be set to 0. †

     Note: Altera recommends that you write 0xFFFFFFFF to the `rintsts` and `idsts` registers to clear any pending interrupts before setting the `int_enable` bit. For internal DMA controller mode, the software driver needs to unmask all the relevant fields in the `idinten` register.†
3. If the software driver needs to use the internal DMA controller to transfer the boot data received, it must perform the following steps: †

- Set up the descriptors as described in *Internal DMA Controller Transmission Sequences* and *Internal DMA Controller Reception Sequences*". †
- Set the use_internal_dmac bit of the ctrl register to 1.†

4. Set the card device frequency to 400 kHz using the clkdiv registers. For more information, refer to Clock Setup.†
5. Set the data_timeout field of the tmout register equal to the card device total access time, N_{AC}. †
6. Set the blksiz register to 0x200 (512 bytes). †
7. Set the bytcnt register to a multiple of 128 KB, as indicated by the BOOT_SIZE_MULT value in the card device.†
8. Set the rx_wmark field in the fifoth register. Typically, the threshold value can be set to 512, which is half the FIFO buffer depth.†
9. Set the following fields in the cmd register:†
    - Initiate the command by setting start_cmd = 1†
    - Enable boot (enable_boot) = 1†
    - Expect boot acknowledge (expect_boot_ack): †
        - If a start-acknowledge pattern is expected from the card device, set expect_boot_ack to 1.†
        - If a start-acknowledge pattern is not expected from the card device, set expect_boot_ack to 0.†
    - Card number (card_number) = 0†
    - data_expected = 1†
    - Reset the remainder of cmd register bits to 0†
10. If no start-acknowledge pattern is expected from the card device (expect_boot_ack set to 0) proceed to **step 12**.†
11. This step handles the case where a start-acknowledge pattern is expected (expect_boot_ack was set to 1 in **step 9**).†

    a. If the Boot ACK Received interrupt is not received from the controller within 50 ms of initiating the command (**step 9**), the software driver must set the following cmd register fields: †

    - start_cmd = 1†
    - Disable boot (disable_boot)= 1†
    - card_number = 0 †
    - All other fields = 0†

    The controller generates a Command Done interrupt after deasserting the CMD pin of the card interface.†

    If internal DMA controller mode is used for the boot process, the controller performs the following steps after the Boot ACK Received timeout:†

    - The DMA descriptor is closed.†
    - The ces bit in the idsts register is set, indicating the Boot ACK Received timeout.†
    - The ri bit of the idsts register is not set.†

    b. If the Boot ACK Received interrupt is received, the software driver must clear this interrupt by writing 1 to the ces bit in the idsts register.†

    Within 0.95 seconds of the Boot ACK Received interrupt, the Boot Data Start interrupt must be received from the controller. If this does not occur, the software driver must write the following cmd register fields:†

    - start_cmd = 1†
    - disable_boot = 1†
    - card_number = 0†
    - All other fields = 0†

The controller generates a Command Done interrupt after deasserting the `CMD` pin of the card interface.†

If internal DMA controller mode is used for the boot process, the controller performs the following steps after the Boot ACK Received timeout:†

- The DMA descriptor is closed†
- The `ces` bit in the `idsts` register is set, indicating Boot Data Start timeout†
- The `ri` bit of the `idsts` register is not set†

c. If the Boot Data Start interrupt is received, it indicates that the boot data is being received from the card device. When the DMA engine is not in internal DMA controller mode, the software driver can then initiate a data read from the controller based on the `rxdr` interrupt bit in the `rintsts` register.†

In internal DMA controller mode, the DMA engine starts transferring the data from the FIFO buffer to the system memory as soon as the level set in the `rx_wmark` field of the `fifoth` register is reached.†

At the end of a successful boot data transfer from the card, the following interrupts are generated:†

- The `cmd` bit and `dto` bit in the `rintsts` register†
- The `ri` bit in the `idsts` register, in internal DMA controller mode only†

d. If an error occurs in the boot ACK pattern (0b010) or an EBE occurs: †

- The controller automatically aborts the boot process by pulling the CMD line high†
- The controller generates a Command Done interrupt†
- The controller does not generate a Boot ACK Received interrupt†
- The application aborts the boot transfer†

e. In internal DMA controller mode:†

- If the software driver creates more descriptors than required by the received boot data, the extra descriptors are not closed by the controller. Software cannot reuse the descriptors until they are closed.†
- If the software driver creates fewer descriptors than required by the received boot data, the controller generates a Descriptor Unavailable interrupt and does not transfer any further data to system memory.†

f. If N_{AC} is violated between data block transfers, the DRTO interrupt is asserted. In addition, if there is an error associated with the start or end bit, the SBE or EBE interrupt is also generated.†

The boot operation for eMMC card devices is complete. Do not execute the remaining (**step 12**).†

12. This step handles the case where no start-acknowledge pattern is expected (`expect_boot_ack` was set to 0 in **step 9**).†

a. If the Boot Data Start interrupt is not received from the controller within 1 second of initiating the command (**step 9**), the software driver must write the `cmd` register with the following fields:†

- `start_cmd` = 1†
- `disable_boot` = 1†
- `card_number` = 0†
- All other fields = 0†

The controller generates a Command Done interrupt after deasserting the CMD line of the card. In internal DMA controller mode, the descriptor is closed and the `ces` bit in the `idsts` register is set to 1, indicating a Boot Data Start timeout.†

b. If a Boot Data Start interrupt is received, it indicates that the boot data is being received from the card device. When the DMA engine is not in internal DMA controller mode, the software driver can then initiate a data read from the controller based on the `rxdr` interrupt bit in the `rintsts` register.†

In internal DMA controller mode, the DMA engine starts transferring the data from the FIFO buffer to the system memory as soon as the level specified in the `rx_wmark` field of the `fifoth` register is reached.†

At the end of a successful boot data transfer from the card, the following interrupts are generated:†

- The `cmd` bit and `dto` bit in the `rintsts` register†
- The `ri` bit in the `idsts` register, in internal DMA controller mode only†

c. In internal DMA controller mode:†

- If the software driver creates more descriptors than required by the received boot data, the extra descriptors are not closed by the controller.†
- If the software driver creates fewer descriptors than required by the received boot data, the controller generates a Descriptor Unavailable interrupt and does not transfer any further data to system memory.†

The boot operation for eMMC card devices is complete.†

Boot Operation for Removable MMC4.3, MMC4.4 and MMC4.41 Cards

Removable MMC4.3, MMC4.4, and MMC4.41 Differences

Removable MMC4.3, MMC4.4, and MMC4.41 cards differ with respect to eMMC in that the controller is not aware whether these cards support the boot mode of operation when plugged in. Thus, the controller must: †

1. Discover these cards as it would discover MMC4.0/4.1/4.2 cards for the first time†
2. Know the card characteristics †
3. Decide whether to perform a boot operation or not†

Booting Removable MMC4.3, MMC4.4 and MMC4.41 Cards

For removable MMC4.3, MMC4.4 and MMC4.41 cards, the software driver must perform the following steps:†

1. Discover the card as described in *Enumerated Card Stack*.†
2. Read the EXT_CSD register of the card and examine the following fields: †
   - BOOT_PARTITION_ENABLE †
   - BOOT_SIZE_MULT†
   - BOOT_INFO †
3. If necessary, the software can manipulate the boot information in the card. †

   Note: For more information, refer to "Access to Boot Partition" in the following specifications available on the JEDEC website:

- JEDEC Standard No. 84-A441
- JEDEC Standard No. 84-A44
- JEDEC Standard No. JESD84-A43

4. If the host processor needs to perform a boot operation at the next power-up cycle, it can manipulate the EXT_CSD register contents by using a SWITCH_FUNC command. †
5. After this step, the software driver must power down the card by writing to the `pwren` register. †
6. From here on, use the same steps as in *Alternative Boot Operation for eMMC Card Devices*.†

Related Information

- **Enumerated Card Stack** on page 14-38
  Refer to this section for more information on discovering removable MMC cards.
- **http://www.jedec.org**
- **Alternative Boot Operation for eMMC Card Devices** on page 14-74
  Refer to this section for information about alternative boot operation steps.

Alternative Boot Operation

The alternative boot operation differs from the previous boot operation in that software uses the SD/SDIO GO_IDLE_STATE command to boot the card, rather than holding down the CMD line of the card. The alternative boot operation can be performed only if bit 0 in the BOOT_INFO register is set to 1. BOOT_INFO is located at offset 228 in the EXT_CSD registers. †

For detailed information about alternative boot operation, refer to the following specifications available on the JEDEC website:

- JEDEC Standard No. 84-A441
- JEDEC Standard No. 84-A44
- JEDEC Standard No. JESD84-A43

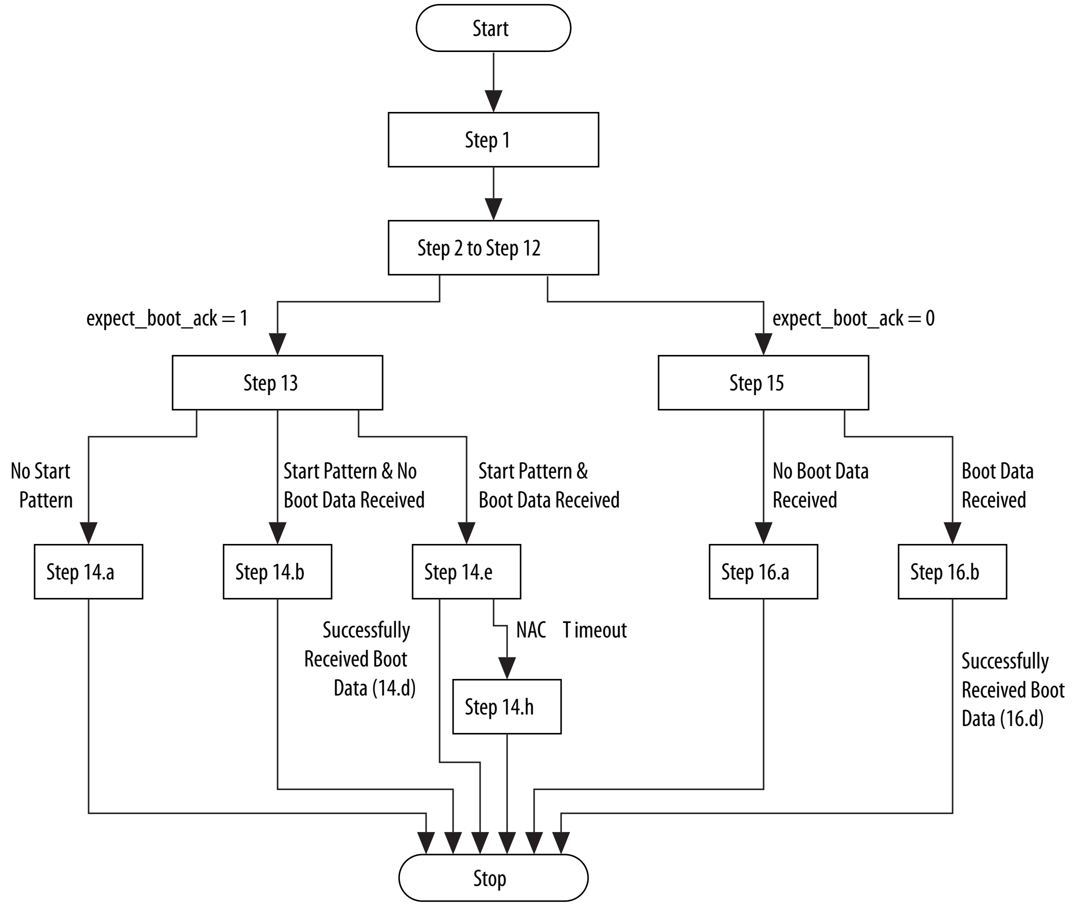
Related Information

www.jedec.org
For more information about alternative boot operation, refer to the following JEDEC Standards available on the JEDEC website: No. 84-A441, No. 84-A44, and No. JESD84-A43.

Alternative Boot Operation for eMMC Card Devices

The following figure illustrates the sequence of steps required to perform the alternative boot operation for eMMC card devices. The detailed steps are described following the flow chart.

Figure 14-16: Flow for eMMC Alternative Boot Operation[†]



1. The software driver checks:[†]
   - If the eMMC card device supports alternative boot operation (the BOOT_INFO bit is set to 1 in the eMMC card).[†]
   - The BOOT_SIZE_MULT and BOOT_BUS_WIDTH values in the card device to use during the boot process.[†]
2. The software sets the following bits: [†]
   - Sets masks for interrupts by resetting the appropriate bits to 0 in the `intmask` register.[†]
   - Sets the `int_enable` bit of the `ctrl` register to 1. Other bits in the `ctrl` register must be set to 0. [†]

   Note: Altera recommends writing 0xFFFFFFFF to the `rintsts` register and `idsts` register to clear any pending interrupts before setting the `int_enable` bit. For internal DMA controller mode, the software driver needs to unmask all the relevant fields in the `idinten` register.[†]
3. If the software driver needs to use the internal DMA controller to transfer the boot data received, it must perform the following actions: [†]
   - Set up the descriptors as described in *Internal DMA Controller Transmission Sequences* and *Internal DMA Controller Reception Sequences.* [†]
   - Set the use internal DMAC bit (`use_internal_dmac`) of the `ctrl` register to 1. [†]
4. Set the card device frequency to 400 kHz using the `clkdiv` registers. For more information, refer to *Clock Setup*. Ensure that the card clock is running.[†]

5. Wait for a time that ensures that at least 74 card clock cycles have occurred on the card interface.†
6. Set the `data_timeout` field of the `tmout` register equal to the card device total access time, N_{AC}. †
7. Set the `blksiz` register to 0x200 (512 bytes).†
8. Set the `bytcnt` register to multiples of 128K bytes, as indicated by the BOOT_SIZE_MULT value in the card device.†
9. Set the `rx_wmark` field in the `fifoth` register. Typically, the threshold value can be set to 512, which is half the FIFO buffer depth.†
10. Set the `cmdarg` register to 0xFFFFFFFA. †
11. Initiate the command, by setting the `cmd` register with the following fields: †

    - `start_cmd` = 1†
    - `enable_boot` = 1†
    - `expect_boot_ack`:†
        - If a start-acknowledge pattern is expected from the card device, set `expect_boot_ack` to 1.†
        - If a start-acknowledge pattern is not expected from the card device, set `expect_boot_ack` to 0. †
    - `card_number` = 0 †
    - `data_expected` = 1†
    - `cmd_index` = 0†
    - Set the remainder of `cmd` register bits to 0.†
12. If no start-acknowledge pattern is expected from the card device (`expect_boot_ack` set to 0) jump to **step 15**. †
13. Wait for the Command Done interrupt.†
14. This step handles the case where a start-acknowledge pattern is expected (`expect_boot_ack` was set to 1 in **step 11**).†

    a. If the Boot ACK Received interrupt is not received from the controller within 50 ms of initiating the command (**step 11**), the start pattern was not received. The software driver must discontinue the boot process and start with normal discovery. †

    If internal DMA controller mode is used for the boot process, the controller performs the following steps after the Boot ACK Received timeout:†

    - The DMA descriptor is closed.†
    - The `ces` bit in the `idsts` register is set to 1, indicating the Boot ACK Received timeout.†
    - The `ri` bit of the `idsts` register is not set.†

    b. If the Boot ACK Received interrupt is received, the software driver must clear this interrupt by writing 1 to it. †

    Within 0.95 seconds of the Boot ACK Received interrupt, the Boot Data Start interrupt must be received from the controller. If this does not occur, the software driver must discontinue the boot process and start with normal discovery.†

    If internal DMA controller mode is used for the boot process, the controller performs the following steps after the Boot ACK Received timeout: †

    - The DMA descriptor is closed.†
    - The `ces` bit in the `idsts` register is set to 1, indicating Boot Data Start timeout.†
    - The `ri` bit of the `idsts` register is not set.†

    c. If the Boot Data Start interrupt is received, it indicates that the boot data is being received from the card device. When the DMA engine is not in internal DMA controller mode, the software driver can then initiate a data read from the controller based on the `rxdr` interrupt bit in the `rintsts` register.†

In internal DMA controller mode, the DMA engine starts transferring the data from the FIFO buffer to the system memory as soon as the level specified in the `rx_wmark` field of the `fifoth` register is reached. †

d. The software driver must terminate the boot process by instructing the controller to send the SD/SDIO GO_IDLE_STATE command:†

  - Reset the `cmdarg` register to 0.†
  - Set the `start_cmd` bit of the `cmd` register to 1, and all other bits to 0.†

e. At the end of a successful boot data transfer from the card, the following interrupts are generated: †

  - The `cmd` bit and `dto` bit in the `rintsts` register†
  - The `ri` bit in the `idsts` register, in internal DMA controller mode only†

f. If an error occurs in the boot ACK pattern (0b010) or an EBE occurs: †

  - The controller does not generate a Boot ACK Received interrupt. †
  - The controller detects Boot Data Start and generates a Boot Data Start interrupt. †
  - The controller continues to receive boot data. †
  - The application must abort the boot process after receiving a Boot Data Start interrupt.†

g. In internal DMA controller mode: †

  - If the software driver creates more descriptors than required by the received boot data, the extra descriptors are not closed by the controller. †
  - If the software driver creates fewer descriptors than required by the received boot data, the controller generates a Descriptor Unavailable interrupt and does not transfer any further data to system memory.†

h. If N_{AC} is violated between data block transfers, a DRTO interrupt is asserted. Apart from this, if there is an error associated with the start or end bit, the SBE or EBE interrupt is also generated.†

The alternative boot operation for eMMC card devices is complete. Do not execute the remaining steps (15 and 16). †

15. Wait for the Command Done interrupt.†
16. This step handles the case where a start-acknowledge pattern is not expected (`expect_boot_ack` was set to 0 in **step 11**). †

a. If the Boot Data Start interrupt is not received from the controller within 1 second of initiating the command (**step 11**), the software driver must discontinue the boot process and start with normal discovery. † In internal DMA controller mode:†

  - The DMA descriptor is closed.†
  - The `ces` bit in the `idsts` register is set to 1, indicating Boot Data Start timeout.†
  - The `ri` bit of the `idsts` register is not set.†

b. If a Boot Data Start interrupt is received, the boot data is being received from the card device. When the DMA engine is not in internal DMA controller mode, the software driver can then initiate a data read from the controller based on the `rxdr` interrupt bit in the `rintsts` register.†

In internal DMA controller mode, the DMA engine starts transferring the data from the FIFO buffer to the system memory as soon as the level specified in the `rx_wmark` field of the `fifoth` register is reached.†

c. The software driver must terminate the boot process by instructing the controller to send the SD/SDIO GO_IDLE_STATE (CMD0) command: †

  - Reset the `cmdarg` register to 0.†
  - Set the `start_cmd` bit in the `cmd` register to 1, and all other bits to 0.†

d. At the end of a successful boot data transfer from the card, the following interrupts are generated: †

- The `cmd` bit and `dto` bit in the `rintsts` register†
- The `ri` bit in the `idsts` register, in internal DMA controller mode only †

e. In internal DMA controller mode: †

- If the software driver creates more descriptors than required by the received boot data, the extra descriptors are not closed by the controller. †
- If the software driver creates fewer descriptors than required by the received boot data, the controller generates a Descriptor Unavailable interrupt and does not transfer any further data to system memory.†

The alternative boot operation for eMMC card devices is complete.†

Alternative Boot Operation for MMC4.3 Cards

Removable MMC4.3 Boot Mode Support

Removable MMC4.3 cards differ with respect to eMMC in that the controller is not aware whether these cards support the boot mode of operation. Thus, the controller must: †

1. Discover these cards as it would discover MMC4.0/4.1/4.2 cards for the first time †
2. Know the card characteristics †
3. Decide whether to perform a boot operation or not†

Discovering Removable MMC4.3 Boot Mode Support

For removable MMC4.3 cards, the software driver must perform the following steps: †

1. Discover the card as described in *Enumerated Card Stack*.†
2. Read the MMC card device's EXT_CSD registers and examine the following fields: †
   - BOOT_PARTITION_ENABLE †
   - BOOT_SIZE_MULT †
   - BOOT_INFO †

   Note: For more information, refer to "Access to Boot Partition" in JEDEC Standard No. JESD84-A43, available on the JEDEC website.†
3. If the host processor needs to perform a boot operation at the next power-up cycle, it can manipulate the contents of the EXT_CSD registers in the MMC card device, by using a SWITCH_FUNC command. †
4. After this step, the software driver must power down the card by writing to the `pwren` register. †
5. From here on, use the same steps as in *Alternative Boot Operation for eMMC Card Devices*. †

   Note: Ignore the EBE if it is generated during an abort scenario.

   If a boot acknowledge error occurs, the boot acknowledge received interrupt times out. †

In internal DMA controller mode, the application needs to depend on the descriptor close interrupt instead of the data done interrupt. †

Voltage Switches

This section describes the general steps to switch voltage level.

The SD/MMC cards support various operating voltages, for example 1.8V and 3.3V. If you have a card which is at 1.8V and you eject it and replace it with another card, which is 3.3V, then voltage switching is required.

In order to have the right voltage level to power the card, separate devices on the board are required: voltage translation transceiver and power regulator/supply. When the software is aware that voltage switching is needed, it should control the power regulator to supply another voltage level to the card (i.e. switching between 1.8V and 3.3V).

However, for the HPS (or Altera device), the I/O pins are connected to the SD/MMC card running at 3.3V. If your card runs at 1.8V, the voltage-translation transceiver is needed for voltage translation between the HPS and the SD/MMC card.

The general steps to switch voltage level requires you to use a SD/MMC voltage-translation transceiver in between the HPS and the SD/MMC card.

1. Power the HPS I/O pins for the SD/MMC controller to 3.3V.
   a. Connect the same power supply to one of the transceiver voltage input pins.
2. Power the other transceiver voltage input pin with another power supply.
   a. Connect this power supply with the SD/MMC card.
3. The SD/MMC will send predefined commands to check if the card supports dual voltage. The response from the card will indicate if dual voltage is supported
4. Software stops all SD/MMC activity. If the card does not support dual voltage, do not perform the remaining steps.
5. The GPIO on HPS sends a signal to the external power supply on the board notifying it to switch its voltage value.
6. After voltage switching is completed, resume the SD/MMC activity.

SD/MMC Controller Address Map and Register Definitions

The address map and register definitions for the SD/MMC Controller consists of the following region:

- SD/MMC Module

SDMMC Module Address Map

Registers in the SD/MMC module

Base Address: `0xFF704000`

SDMMC Module

Register	Offset	Width	Acces s	Reset Value	Description

ctrl

Sets various operating condiitions.

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF704000

Offset: 0x0

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved						use_internal_dmac RW 0x0	Reserved								
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved				ceata_device_interrupt_status RW 0x0	send_auto_stop_ccsd RW 0x0	send_ccsd RW 0x0	abort_read_data RW 0x0	send_irq_response RW 0x0	read_wait RW 0x0	Reserved	int_enable RW 0x0	Reserved	dma_reset RW 0x0	fifo_reset RW 0x0	controller_reset RW 0x0

ctrl Fields

Bit	Name	Description	Access	Reset
25	use_internal_dmac	Enable and Disable Internal DMA transfers. **Value** **Description** 0x0 The host performs data transfers thru slave interface 0x1 Internal DMAC used for data transfer	RW	0x0
11	ceata_device_ interrupt_status	Software should appropriately write to this bit after power-on reset or any other reset to CE-ATA device. After reset, usually CE-ATA device interrupt is disabled (nIEN = 1). If the host enables CE-ATA device interrupt, then software should set this bit. **Value** **Description** 0x0 Interrupts not enabled in CE-ATA device 0x1 Interrupts are enabled in CE-ATA device	RW	0x0

Bit	Name	Description	Access	Reset
10	`send_auto_stop_ccsd`	Always set send_auto_stop_ccsd and send_ccsd bits together; send_auto_stop_ccsd should not be set independent of send_ccsd. When set, SD/MMC automatically sends internally generated STOP command (CMD12) to CE-ATA device. After sending internally-generated STOP command, Auto Command Done (ACD) bit in RINTSTS is set and generates interrupt to host if Auto CommandDone interrupt is not masked. After sending the CCSD, SD/MMC automatically clears send_auto_stop_ccsd bit. **Value** **Description** 0x0 Clear bit if SD/MMC does not reset the bit 0x1 Send internally generated STOP.	`RW`	`0x0`
9	`send_ccsd`	When set, SD/MMC sends CCSD to CE-ATA device. Software sets this bit only if current command is expecting CCS (that is, RW_BLK) and interrupts are enabled in CE-ATA device. Once the CCSD pattern is sent to device, SD/MMC automatically clears send_ccsd bit. It also sets Command Done (CD) bit in RINTSTS register and generates interrupt to host if Command Done interrupt is not masked. NOTE: Once send_ccsd bit is set, it takes two card clock cycles to drive the CCSD on the CMD line. Due to this, during the boundary conditions it may happen that CCSD is sent to the CE-ATA device, even if the device signalled CCS. **Value** **Description** 0x0 Clear bit if SD/MMC does not reset the bit 0x1 Send Command Completion Signal Disable (CCSD) to CE-ATA device	`RW`	`0x0`
8	`abort_read_data`	After suspend command is issued during read-transfer, software polls card to find when suspend happened. Once suspend occurs software sets bit to reset data state-machine, which is waiting for next block of data. Bit automatically clears once data statemachine resets to idle. Used in SDIO card suspend sequence. **Value** **Description** 0x0 No change 0x1 Abort Read	`RW`	`0x0`

Bit	Name	Description	Access	Reset
7	`send_irq_response`	Bit automatically clears once response is sent. To wait for MMC card interrupts, host issues CMD40, and SD/MMC waits for interrupt response from MMC card(s). In meantime, if host wants SD/MMC to exit waiting for interrupt state, it can set this bit, at which time SD/MMC command state-machine sends CMD40 response on bus and returns to idle state. **Value** **Description** 0x0 No change 0x1 Send auto IRQ response	RW	0x0
6	`read_wait`	For sending read-wait to SDIO cards. **Value** **Description** 0x0 Read Wait 0x1 Assert Read Wait	RW	0x0
4	`int_enable`	This bit enables and disable interrupts if one or more unmasked interrupts are set. **Value** **Description** 0x0 Disable Interrupts 0x1 Enable interrupts	RW	0x0
2	`dma_reset`	This bit resets the DMA interface control logic **Value** **Description** 0x0 No change 0x1 Reset internal DMA interface control logic	RW	0x0
1	`fifo_reset`	This bit resets the FIFO. This bit is auto-cleared after completion of reset operation. **Value** **Description** 0x0 No change 0x1 Reset to data FIFO To reset FIFO pointers	RW	0x0

Bit	Name	Description	Access	Reset
0	`controller_reset`	This bit resets the controller. This bit is auto-cleared after two l4_mp_clk and two sdmmc_clk clock cycles. This resets: - BIU/CIU interface - CIU and state machines - abort_read_data, send_irq_response, and read_wait bits of control register -start_cmd bit of command register Does not affect any registers, DMA interface, FIFO or host interrupts. **Value** **Description** 0x0 No change -default 0x1 Reset SD/MMC controller	RW	0x0

pwren

Power on/off switch for card; once power is turned on, firmware should wait for regulator/switch ramp-up time before trying to initialize card.

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF704004

Offset: `0x4`

Access: `RW`

Bit Fields

Reserved															power_enable RW 0x0

pwren Fields

Bit	Name	Description	Access	Reset
0	`power_enable`	Power on/off switch for one card; for example, bit[0] controls the card. Once power is turned on, firmware should wait for regulator/switch ramp-up time before trying to initialize card. **Value** **Description** 0x0 Power Off 0x1 Power On	RW	0x0

clkdiv

Divides Clock sdmmc_clk.

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF704008

Offset: 0x8

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
Reserved															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
Reserved								clk_divider0 RW 0x0							

clkdiv Fields

Bit	Name	Description	Access	Reset
7:0	clk_divider0	Clock divider-0 value. Clock division is 2*n. For example, value of 0 means divide by 2*0 = 0 (no division, bypass), value of 1 means divide by 2*1 = 2, value of ff means divide by 2*255 = 510, and so on.	RW	0x0

clksrc

Selects among available clock dividers. The sdmmc_cclk_out is always from clock divider 0.

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF70400C

Offset: 0xC

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16

block_size RW 0x200															

blksiz Fields

Bit	Name	Description	Access	Reset
15:0	block_size	The size of a block in bytes.	RW	0x200

bytcnt

The number of bytes to be transferred.

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF704020

Offset: 0x20

Access: RW

Bit Fields															
31	30	29	28	27	26	25	24	23	22	21	20	19	18	17	16
byte_count RW 0x200															
15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
byte_count RW 0x200															

bytcnt Fields

Bit	Name	Description	Access	Reset
31:0	byte_count	This value should be an integer multiple of the Block Size for block transfers. For undefined number of byte transfers, byte count should be set to 0. When byte count is set to 0, it is responsibility of host to explicitly send stop/abort command to terminate data transfer. Note: In SDIO mode, if a single transfer is greater than 4 bytes and non-DWORD-aligned, the transfer should be broken where only the last transfer is non-DWORD-aligned and less than 4 bytes. For example, if a transfer of 129 bytes must occur, then the driver should start at least two transfers; one with 128 bytes and the other with 1 byte.	RW	0x200

intmask

Allows Masking of Various Interrupts

Module Instance	Base Address	Register Address
sdmmc	0xFF704000	0xFF704024

Offset: 0x24

Access: RW

cmd Fields

Bit	Name	Description	Access	Reset
31	start_cmd	Once command is taken by CIU, bit is cleared. If Start Cmd issued host should not attempt to write to any command registers. If write is attempted, hardware lock error is set in raw interrupt register. Once command is sent and response is received from SD_MMC_CEATA cards, Command Done bit is set in raw interrupt register. **Value** — **Description** 0x0 — No Start Cmd 0x1 — Start Cmd Issued	RW	0x0
29	use_hold_reg	Set to one for SDR12 and SDR25 (with non-zero phase-shifted cclk_in_drv); zero phase shift is not allowed in these modes. -Set to 1'b0 for SDR50, SDR104, and DDR50 (with zero phase-shifted cclk_in_drv). -Set to 1'b1 for SDR50, SDR104, and DDR50 (with non-zero phase-shifted cclk_in_drv). **Value** — **Description** 0x0 — CMD and DATA sent to card bypassing HOLD Register 0x1 — CMD and DATA sent to card through the HOLD Register	RW	0x1
28	volt_switch	Voltage switch bit. When set must be set for CMD11 only. **Value** — **Description** 0x0 — No voltage switching - default 0x1 — Voltage switching enabled	RW	0x0
27	boot_mode	Type of Boot Mode. **Value** — **Description** 0x0 — Mandatory Boot Operation 0x1 — Alternate Boot Operation	RW	0x0

Bit	Name	Description	Access	Reset
26	`disable_boot`	When software sets this bit along with start_cmd, CIU terminates the boot operation. Do NOT set disable_boot and enable_boot together. **Value** **Description** 0x0 Boot not Terminated 0x1 Terminate Boot	RW	0x0
25	`expect_boot_ack`	When Software sets this bit along with enable_boot, CIU expects a boot acknowledge start pattern of 0-1-0 from the selected card. **Value** **Description** 0x0 No Boot ACK 0x1 Expect Boot ACK	RW	0x0
24	`enable_boot`	This bit should be set only for mandatory boot mode. When Software sets this bit along with start_cmd, CIU starts the boot sequence for the corresponding card by asserting the CMD line low. Do NOT set disable_boot and enable_boot together **Value** **Description** 0x0 Disable Boot 0x1 Enable Boot	RW	0x0
23	`ccs_expected`	If the command expects Command Completion Signal (CCS) from the CE-ATA device, the software should set this control bit. SD/MMC sets Data Transfer Over (DTO) bit in RINTSTS register and generates interrupt to host if Data Transfer Over interrupt is not masked. **Value** **Description** 0x0 Interrupts are not enabled in CE-ATA device (nIEN = 1 in ATA control register), or command does not expect CCS from device 0x1 Interrupts are enabled in CE-ATA device (nIEN = 0), and RW_BLK command expects command completion signal from CE-ATA device	RW	0x0

Bit	Name	Description	Access	Reset
22	`read_ceata_device`	Software should set this bit to indicate that CE-ATA device is being accessed for read transfer. This bit is used to disable read data timeout indication while performing CE-ATA read transfers. Maximum value of I/O transmission delay can be no less than 10 seconds. SD/MMC should not indicate read data timeout while waiting for data from CE-ATA device. **Value** **Description** 0x0 Host is not performing read access (RW_REG or RW_BLK) towards CE-ATA device 0x1 Host is performing read access (RW_REG or RW_BLK) towards CE-ATA device	RW	0x0
21	`update_clock_registers_only`	Following register values transferred into card clock domain: CLKDIV, CLRSRC, CLKENA. Changes card clocks (change frequency, truncate off or on, and set low-frequency mode); provided in order to change clock frequency or stop clock without having to send command to cards. During normal command sequence, when update_clock_registers_only = 0, following control registers are transferred from BIU to CIU: CMD, CMDARG, TMOUT, CTYPE, BLKSIZ, BYTCNT. CIU uses new register values for new command sequence to card(s). When bit is set, there are no Command Done interrupts because no command is sent to SD_MMC_CEATA cards. **Value** **Description** 0x0 Normal command sequence 0x1 Do not send commands, just update clock register value into card clock domain	RW	0x0
20:16	`card_number`	Card number in use must always be 0.	RW	0x0

Bit	Name	Description	Access	Reset
15	`send_initialization`	After power on, 80 clocks must be sent to the card for initialization before sending any commands to card. Bit should be set while sending first command to card so that controller will initialize clocks before sending command to card. This bit should not be set for either of the boot modes (alternate or mandatory). **Value** **Description** 0x0 Do not send initialization sequence (80 clocks of 1) before sending this command 0x1 Send initialization sequence before sending this command	RW	0x0
14	`stop_abort_cmd`	When open-ended or predefined data transfer is in progress, and host issues stop or abort command to stop data transfer, bit should be set so that command/ data state-machines of CIU can return correctly to idle state. This is also applicable for Boot mode transfers. To Abort boot mode, this bit should be set along with CMD[26] = disable_boot. Note: If abort is sent to function-number currently selected or not in data-transfer mode, then bit should be set to 0. **Value** **Description** 0x0 Don't stop or abort command to stop current data transfer in progress 0x1 Stop or Abort command, intended to stop current data transfer in progress	RW	0x0
13	`wait_prvdata_complete`	Determines when command is sent. The send command at once option is typically used to query status of card during data transfer or to stop current data transfer. **Value** **Description** 0x0 Send command at once 0x1 Wait for previous data transfer completion	RW	0x0

Bit	Name	Description	Access	Reset
12	`send_auto_stop`	When set, SD/MMC sends stop command to SD_MMC_CEATA cards at end of data transfer. Determine the following: *-when send_auto_stop bit should be set, since some data transfers do not need explicit stop commands. *-open-ended transfers that software should explicitly send to stop command. Additionally, when resume is sent to resume-suspended memory access of SD-Combo card, bit should be set correctly if suspended data transfer needs send_auto_stop. Don't care if no data expected from card. **Value** / **Description** 0x0 No stop command sent at end of data transfer 0x1 Send stop command at end of data transfer	RW	0x0
11	`transfer_mode`	Block transfer command. Don't care if no data expected **Value** / **Description** 0x0 Block data transfer command 0x1 Stream data transfer command	RW	0x0
10	`read_write`	Read/Write from card. Don't care if no data transfer expected. **Value** / **Description** 0x0 Read from card 0x1 Write to card	RW	0x0
9	`data_expected`	Set decision on data transfer expecetd or not. **Value** / **Description** 0x0 No data transfer expected (read/write) 0x1 Data transfer expected (read/write)	RW	0x0

Bit	Name	Description	Access	Reset
8	`check_response_crc`	Some of command responses do not return valid CRC bits. Software should disable CRC checks for those commands in order to disable CRC checking by controller. **Value** — **Description** 0x0 — Do not check response CRC 0x1 — Check Response CRC	RW	0x0
7	`response_length`	Provides long and short response **Value** — **Description** 0x0 — Short response expected from card 0x1 — Long response expected from card	RW	0x0
6	`response_expect`	Response expected from card. **Value** — **Description** 0x0 — No response expected from card 0x1 — Response expected from card	RW	0x0
5:0	`cmd_index`	Tracks the command index number. Values from 0-31.	RW	0x0

resp0

Preserves previous command.

</table>

fifoth Fields

Bit	Name	Description	Access	Reset
30:28	dw_dma_multiple_ transaction_size	Burst size of multiple transaction; should be programmed same as DMA controller multiple-transaction-size SRC/DEST_MSIZE. The units for transfers is 32 bits. A single transfer would be signalled based on this value. Value should be sub-multiple of 512. Allowed combinations for MSize and TX_WMark. **Value** — **Description** 0x0 — Msize 1 and TX_WMARK 1-1023 0x1 — Msize 4 and TX_WMARK 256 0x2 — Msize 8 and TX_WMARK 128 0x3 — Msize 16 and TX_WMARK 64 0x5 — Msize 1 and RX_WMARK 512 0x6 — Msize 4 and RX_WMARK 128 0x7 — Msize 8 and RX_WMARK 64	RW	0x0
27:16	rx_wmark	FIFO threshold watermark level when receiving data to card. When FIFO data count reaches greater than this number, DMA/FIFO request is raised. During end of packet, request is generated regardless of threshold programming in order to complete any remaining data. In non-DMA mode, when receiver FIFO threshold (RXDR) interrupt is enabled, then interrupt is generated instead of DMA request. During end of packet, interrupt is not generated if threshold programming is larger than any remaining data. It is responsibility of host to read remaining bytes on seeing Data Transfer Done interrupt. In DMA mode, at end of packet, even if remaining bytes are less than threshold, DMA request does single transfers to flush out any remaining bytes before Data Transfer Done interrupt is set. 12 bits - 1 bit less than FIFO-count of status register, which is 13 bits. Limitation: RX_WMark <= 1022 Recommended: 511; means greater than (FIFO_DEPTH/2) - 1) NOTE: In DMA mode during CCS time-out, the DMA does not generate the request at the end of packet, even if remaining bytes are less than threshold. In this case, there will be some data left in the FIFO. It is the responsibility of the application to reset the FIFO after the CCS timeout.	RW	0x3FF

Bit	Name	Description	Access	Reset
11:0	tx_wmark	FIFO threshold watermark level when transmitting data to card. When FIFO data count is less than or equal to this number, DMA/FIFO request is raised. If Interrupt is enabled, then interrupt occurs. During end of packet, request or interrupt is generated, regardless of threshold programming. In non-DMA mode, when transmit FIFO threshold (TXDR) interrupt is enabled, then interrupt is generated instead of DMA request. During end of packet, on last interrupt, host is responsible for filling FIFO with only required remaining bytes (not before FIFO is full or after CIU completes data transfers, because FIFO may not be empty). In DMA mode, at end of packet, if last transfer is less than burst size, DMA controller does single cycles until required bytes are transferred. 12 bits - 1 bit less than FIFO-count of status register, which is 13 bits. Limitation: TX_WMark >= 1; Recommended: FIFO_DEPTH/2 = 512; (means less than or equal to 512)	RW	0x0

Quad SPI Flash Controller 15

2014.07.31

cv_54012 Subscribe Send Feedback

The hard processor system (HPS) provides a quad serial peripheral interface (SPI) flash controller for access to serial NOR flash devices. The quad SPI flash controller supports standard SPI flash devices as well as high-performance dual and quad SPI flash devices. The quad SPI flash controller is based on Cadence Quad SPI Flash Controller (QSPI_FLASH_CTRL).

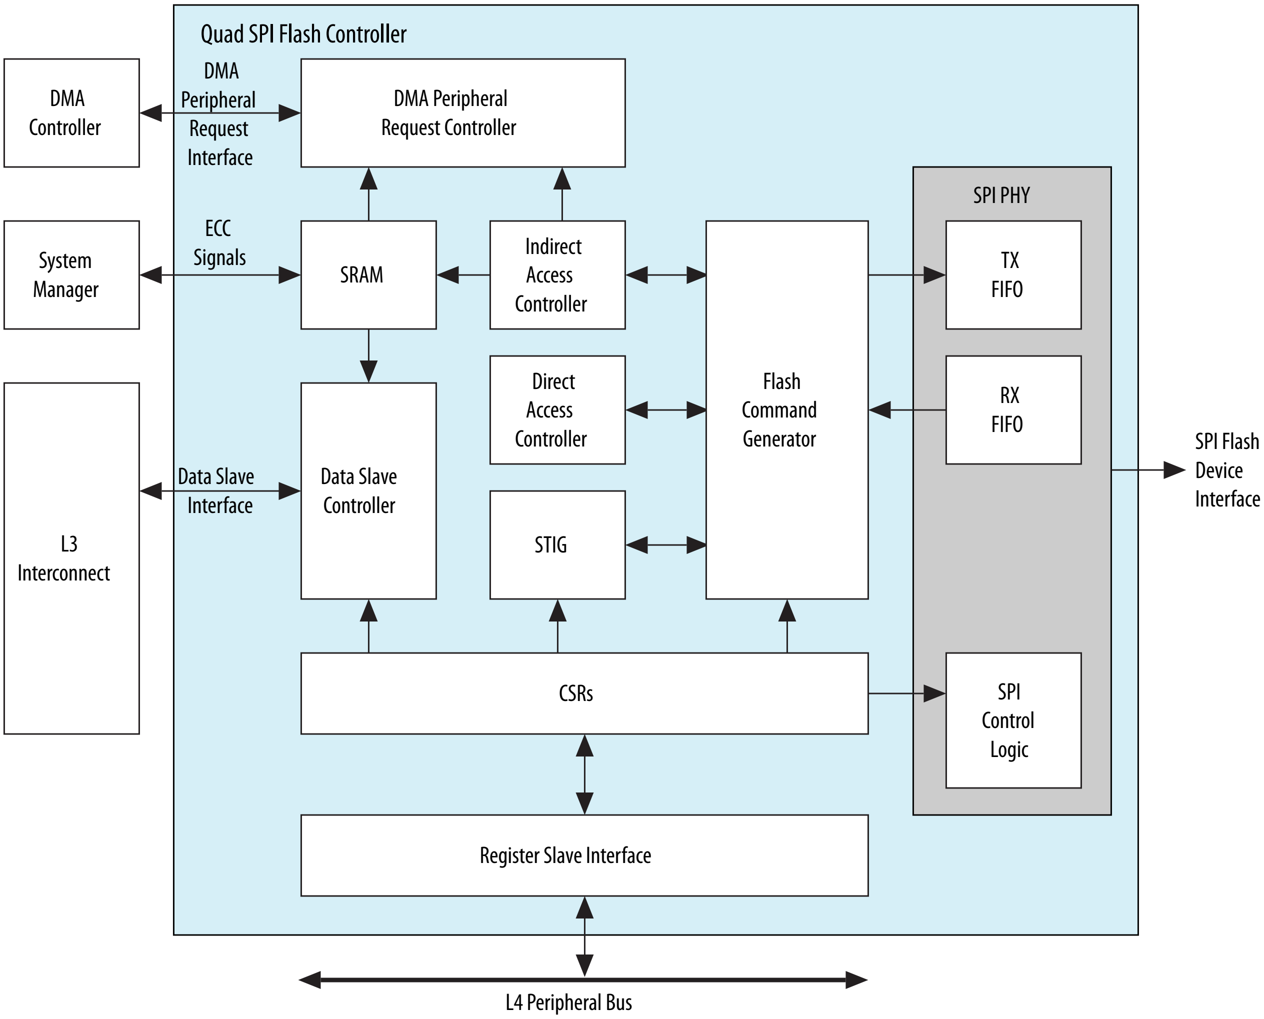
Features of the Quad SPI Flash Controller

The quad SPI flash controller supports the following features:

- Single, dual, and quad I/O commands
- Device frequencies up to 108 MHz
- Direct access and indirect access modes
- External direct memory access (DMA) controller support for indirect transfers
- Configurable clock polarity and phase
- Programmable write-protected regions
- Programmable delays between transactions
- Programmable device sizes
- Read data capture tuning
- Local buffering with error correction code (ECC) logic for indirect transfers
- Up to four devices
- eXecute-In-Place (XIP) mode

Quad SPI Flash Controller Block Diagram and System Integration

Figure 15-1: Quad SPI Flash Controller Block Diagram and System Integration



The quad SPI controller consists of the following blocks and interfaces:

- Register slave interface—Slave interface that provides access to the control and status registers (CSRs)
- Data slave controller—Slave interface and controller that provides the following functionality:
  - Performs data transfers to and from the level 3 (L3) interconnect
  - Validates incoming accesses
  - Performs byte or half-word reordering
  - Performs write protection
  - Forwards transfer requests to direct and indirect controller
- Direct access controller—provides memory-mapped slaves direct access to the flash memory
- Indirect access controller—provides higher-performance access to the flash memory through local buffering and software transfer requests

- Software triggered instruction generator (STIG)—generates flash commands through the flash command register (`flashcmd`) and provides low-level access to flash memory
- Flash command generator—generates flash command and address instructions based on instructions from the direct and indirect access controllers or the STIG
- DMA peripheral request controller—issues requests to the DMA peripheral request interface to communicate with the external DMA controller
- SPI PHY—serially transfers data and commands to the external SPI flash devices

Functional Description of the Quad SPI Flash Controller

Overview

Note: Terms used in this section are defined in detail in the sections that follow.

The quad SPI flash controller uses the register slave interface to select the operation modes and configure the data slave interface for data transfers. The quad SPI flash controller uses the data slave interface for direct and indirect accesses, and the register slave interface for software triggered instruction generator (STIG) operation and SPI legacy mode accesses.

Accesses to the data slave are forwarded to the direct or indirect access controller. If the access address is within the configured indirect address range, the access is sent to the indirect access controller.

Data Slave Interface

The quad SPI flash controller uses the data slave interface for direct, indirect, and SPI legacy mode accesses.

Note:
- The data slave is 32 bits wide.
- Byte, half-word, and word accesses are permitted.
- For write accesses:
  - only incrementing bursts are supported
  - only of sizes 1, 4, 8, and 16 transfers
- For read accesses
  - all burst types and sizes are supported

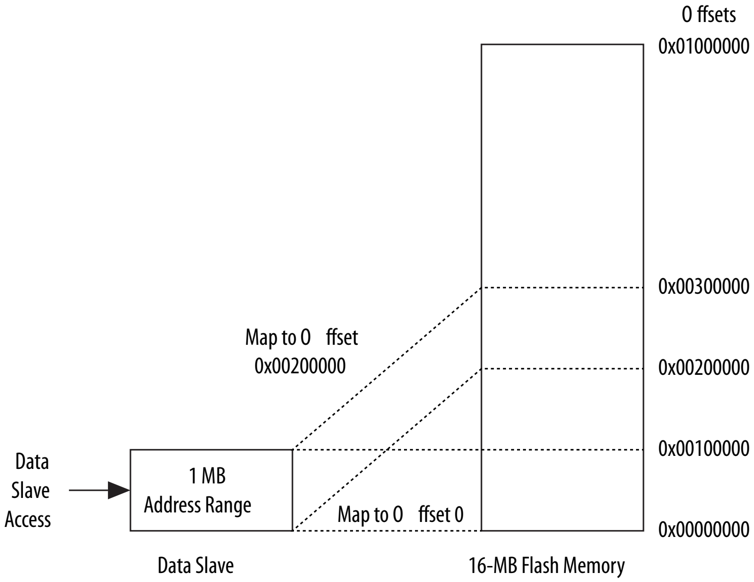
Direct Access Mode

Direct access mode is memory mapped and can be used to both access and directly execute code from external FLASH memory. Any incoming AMBA data slave interface access that is not recognized as being within the programmable indirect trigger region is assumed to be a direct access and is serviced by the direct access controller.

Note: Accesses that use the direct access controller do not use the embedded SRAM.

Data Slave Remapping Example

Figure 15-2: Data Slave Remapping Example



To remap the data slave to access other 1 MB regions of the flash device, enable address remapping in the enable ARM® AMBA® advanced high speed bus (AHB) address remapping field (`enahbremap`) of the `cfg` register. All incoming data slave accesses remap to the offset specified in the remap address register (`remapaddr`).

The 20 LSBs of incoming addresses are used for accessing the 1 MB region and the higher bits are ignored.

Note: The quad SPI controller does not issue any error status for accesses that lie outside the connected flash memory space.

AHB

The data slave interface is throttled as the read or write burst is carried out. The latency is designed to be as small as possible and is kept to a minimum when the use of XIP read instructions are enabled.

FLASH erase operations, which may be required before a page write, are triggered by software using the documented programming interface. They are not issued automatically.

Once a page program cycle has been started, the QSPI Flash Controller will automatically poll for the write cycle to complete before allowing any further data slave interface accesses to complete. This is achieved by holding any subsequent AHB direct accesses in wait state.

Indirect Access Mode

In indirect access mode, flash data is temporarily buffered in the quad SPI controller's static RAM (SRAM). Software controls and triggers indirect accesses through the register slave interface. The controller transfers data through the data slave interface.

Indirect Read Operation

An indirect read operation reads data from the flash memory, places the data into the SRAM, and transfers the data to an external master through the data slave interface. The indirect read operations are controlled by the following registers:

- Indirect read transfer register (`indrd`)
- Indirect read transfer watermark register (`indrdwater`)
- Indirect read transfer start address register (`indrdstaddr`)
- Indirect read transfer number bytes register (`indrdcnt`)
- Indirect address trigger register (`indaddrtrig`)

These registers need to be configured prior to issuing indirect read operations. The start address needs to be defined in the `indrdstaddr` register and the total number of bytes to be fetched is specified in the `indircnt` register. Writing 1 to the start indirect read bit (`start`) of the `indrd` register triggers the indirect read operation from the flash memory to populate the SRAM with the returned data.

To read data from the flash device into the SRAM, an external master issues 32-bit read transactions to the data slave interface. The address of the read access must be in the indirect address range. You can configure the indirect address through the `indaddrtrig` register. The external master can issue 32-bit reads until the last word of an indirect transfer. On the final read, the external master may issue a 32-bit, 16-bit or 8-bit read to complete the transfer. If there are less than four bytes of data to read on the last transfer, the external master can still issue a 32-bit read and the quad SPI controller will pad the upper bits of the response data with zeros.

Assuming the requested data is present in the SRAM at the time the data slave read is received by the quad SPI controller, the data is fetched from SRAM and the response to the read burst is achieved with minimum latency. If the requested data is not immediately present in the SRAM, the data slave interface enters a wait state until the data has been read from flash memory into SRAM. Once the data has been read from SRAM by the external master, the quad SPI controller frees up the associated resource in the SRAM. If the SRAM is full, reads on the SPI interface are backpressured until space is available in the SRAM. The quad SPI controller completes any current read burst, waits for SRAM to free up, and issues a new read burst at the address where the previous burst was terminated.

The processor can also use the SRAM fill level in the SRAM fill register (`sramfill`) to control when data should be fetched from the SRAM.

Another alternative is to use the fill level watermark of the SRAM, which you configure in the `indrdwater` register. When the SRAM fill level passes the watermark level, the indirect transfer watermark interrupt is generated. You can disable the watermark feature by writing zero to the `indrdwater` register.

For the final bytes of data read by the quad SPI controller and placed in the SRAM, if the watermark level is greater than zero, the indirect transfer watermark interrupt is generated even when the actual SRAM fill level has not risen above the watermark.

If the address of the read access is outside the range of the indirect trigger address, one of the following actions occurs:

- When direct access mode is enabled, the read uses direct access mode.
- When direct access mode is disabled, the slave returns an error back to the requesting master.

You can cancel an indirect operation by setting the cancel indirect read bit (`cancel`) of the `indrd` register to 1. For more information, refer to the *"Indirect Read Operation with DMA Disabled"* section.

Related Information

Indirect Read Operation with DMA Disabled on page 15-15

Indirect Write Operation

An indirect write operation programs data from the SRAM to the flash memory. The indirect write operations are controlled by the following registers:

- Indirect write transfer register (`indwr`)
- Indirect write transfer watermark register (`indwrwater`)
- Indirect write transfer start address register (`indwrstaddr`)
- Indirect write transfer number bytes register (`indwrcnt`)
- `indaddrtrig` register

These registers need to be configured prior to issuing indirect write operations. The start address needs to be defined in the `indwrstaddr` register and the total number of bytes to be written is specified in the `indwrcnt` register. The start indirect write bit (`start`) of the `indwr` register triggers the indirect write operation from the SRAM to the flash memory.

To write data from the SRAM to the flash device, an external master issues 32-bit write transactions to the data slave. The address of the write access must be in the indirect address range. You can configure the indirect address through the `indaddrtrig` register. The external master can issue 32-bit writes until the last word of an indirect transfer. On the final write, the external master may issue a 32-bit, 16-bit or 8-bit write to complete the transfer. If there are less than four bytes of data to write on the last transfer, the external master can still issue a 32-bit write and the quad SPI controller discards the extra bytes.

The SRAM size can limit the amount of data that the quad SPI controller can accept from the external master. If the SRAM is not full at the point of the write access, the data is pushed to the SRAM with minimum latency. If the external master attempts to push more data to the SRAM than the SRAM can accept, the quad SPI controller backpressures the external master with wait states. When the SRAM resource is freed up by pushing the data from SRAM to the flash memory, the SRAM is ready to receive more data from the external master. When the SRAM holds an equal or greater number of bytes than the size of a flash page, or when the SRAM holds all the remaining bytes of the current indirect transfer, the quad SPI controller initiates a write operation to the flash memory.

The processor can also use the SRAM fill level, in the `sramfill` register, to control when to write more data into the SRAM.

Alternatively, you can configure the fill level watermark of the SRAM in the `indwrwater` register. When the SRAM fill level falls below the watermark level, an indirect transfer watermark interrupt is generated to tell software to write the next page of data to SRAM. Because the quad SPI controller initiates non-end-of-data writes to the flash memory only when the SRAM contains a full flash page of data, you must set the watermark level to a value greater than one flash page to avoid the system stalling. You can disable the watermark feature by writing zero to the `indwrwater` register.

If the address of the write access is outside the range of the indirect trigger address, one of the following actions occurs:

- When direct access mode is enabled, the write uses direct access mode.
- When direct access mode is disabled, the slave returns an error back to the requesting master.

You can cancel an indirect operation by setting the cancel indirect write bit (`cancel`) of the `indwr` register to 1. For more information, refer to the *"Indirect Write Operation with DMA Disabled"* section.

Related Information

Indirect Write Operation with DMA Disabled on page 15-16

Consecutive Reads and Writes

It is possible to trigger two indirect operations at a time by triggering the `start` bit of the `indrd` or `indwr` register twice in short succession. The second operation can be triggered while the first operation is in progress. For example, software may trigger an indirect read or write operation while an indirect write operation is in progress. The corresponding start and count registers must be configured properly before software triggers each transfer operation.

This approach allows for a short turnaround time between the completion of one indirect operation and the start of a second operation. Any attempt to queue more than two operations causes the indirect read reject interrupt to be generated.

SPI Legacy Mode

SPI legacy mode allows software to access the internal TX FIFO and RX FIFO buffers directly, thus bypassing the direct, indirect and STIG controllers. Software accesses the TX FIFO and RX FIFO buffers by writing any value to any address through the data slave while legacy mode is enabled. You can enable legacy mode with the legacy IP mode enable bit (`enlegacyip`) of the `cfg` register.

Legacy mode allows the user to issue any flash instruction to the flash device, but imposes a heavy software overhead in order to manage the fill levels of the FIFO buffers effectively. The legacy SPI mode is bidirectional in nature, with data continuously being transferred both directions while the chip select is enabled. If the driver only needs to read data from the flash device, dummy data must be written to ensure the chip select stays active, and vice versa for write transactions.

For example, to perform a basic read of four bytes to a flash device that has three address bytes, software must write a total of eight bytes to the TX FIFO buffer. The first byte would be the instruction opcode, the next three bytes are the address, and the final four bytes would be dummy data to ensure the chip select stays active while the read data is returned. Similarly, because eight bytes were written to the TX FIFO buffer, software should expect eight bytes to be returned in the RX FIFO buffer. The first four bytes of this would be discarded, leaving the final four bytes holding the data read from the device.

Because the TX FIFO and RX FIFO buffers are four bytes deep each, software must maintain the FIFO buffer levels to ensure the TX FIFO buffer does not underflow and the RX FIFO buffer does not overflow. Interrupts are provided to indicate when the fill levels pass the watermark levels, which are configurable through the TX threshold register (`txtresh`) and RX threshold register (`rxtresh`).

Register Slave Interface

The quad SPI flash controller uses the register slave interface to configure the quad SPI controller through the quad SPI configuration registers, and to access flash memory under software control, through the `flashcmd` register in the STIG.

STIG Operation

The Software Triggered Instruction Generator (STIG) is used to access the volatile and non-volatile configuration registers, the legacy SPI status register, and other status and protection registers. The STIG also is used to perform ERASE functions. The direct and indirect access controllers are used only to transfer data. The `flashcmd` register uses the following parameters to define the command to be issued to the flash device:

- Instruction opcode
- Number of address bytes
- Number of dummy bytes
- Number of write data bytes
- Write data
- Number of read data bytes

The address is specified through the flash command address register (`flashcmdaddr`). Once these settings have been specified, software can trigger the command with the execute command field (`execcmd`) of the flashcmd register and wait for its completion by polling the command execution status bit (cmdexecstat) of the flashcmd register. A maximum of eight data bytes may be read from the flash command read data lower (flashcmdrddatalo) and flash command read data upper (flashcmdrddataup) registers or written to the flash command write data lower (flashcmdwrdatalo) and flash command write data upper (flashcmdwrdataup) registers per command.

Commands issued through the STIG have a higher priority than all other read accesses and therefore interrupt any read commands being requested by the direct or indirect controllers. However, the STIG does not interrupt a write sequence that may have been issued through the direct or indirect access controller. In these cases, it might take a long time for the cmdexecstat bit of the flashcmd register indicates the operation is complete.

Note: Altera recommends using the STIG instead of the SPI legacy mode to access the flash device registers and perform erase operations.

Local Memory Buffer

The SRAM local memory buffer is a 128 by 32-bit (512 total bytes) memory and includes support for error correction code (ECC). The ECC logic provides outputs to notify the system manager when single-bit correctable errors are detected (and corrected) and when double-bit uncorrectable errors are detected. The ECC logic also allows the injection of single- and double-bit errors for test purposes.

The SRAM has two partitions, with the lower partition reserved for indirect read operations and the upper partition for indirect write operations, as shown in **Figure 15-1**. The size of the partitions is specified in the SRAM partition register (srampart), based on 32-bit word sizes. For example, to specify four bytes of storage, write the value 1. The value written to the indirect read partition size field (addr) defines the number of entries reserved for indirect read operations. For example, write the value 32 (0x20) to partition the 128-entry SRAM to 32 entries (25%) for read usage and 96 entries (75%) for write usage.

For more information about ECC, refer to the *System Manager* chapter in volume 3 of the Cyclone® V Device Handbook.

System Manager on page 5-1

DMA Peripheral Request Controller

The DMA peripheral request controller is only used for the indirect mode of operation where data is temporarily stored in the SRAM. The quad SPI flash controller uses the DMA peripheral request interface to trigger the external DMA into performing data transfers between memory and the quad SPI controller.

There are two DMA peripheral request interfaces, one for indirect reads and one for indirect writes. The DMA peripheral request controller can issue two types of DMA requests, single or burst, to the external DMA. The number of bytes for each single or burst request is specified in the number of single bytes (numsglreqbytes) and number of burst bytes (numburstreqbytes) fields of the DMA peripheral register (dmaper). The DMA peripheral request controller splits the total amount of data to be transferred into a number of DMA burst and single requests by dividing the total number of bytes by the number of bytes specified in the burst request, and then dividing the remainder by the number of bytes in a single request.

Note: When programming the DMA controller, the burst request size must match the burst request size set in the quad SPI controller to avoid quickly reaching an overflow or underflow condition.

For indirect reads, the DMA peripheral request controller only issues DMA requests after the data has been retrieved from flash memory and written to SRAM. The rate at which DMA requests are issued depends on the watermark level. The indrdwater register defines the minimum fill level in bytes at which the DMA peripheral request controller can issue the DMA request. The higher this number is, the more data that must be buffered in SRAM before the external DMA moves the data. When the SRAM fill level passes the watermark level, the transfer watermark reached interrupt is generated.

For example, consider the following conditions:

- The total amount of data to be read using indirect mode is 256 bytes
- The SRAM watermark level is set at 128 bytes
- Software configures the burst type transfer size to 64 bytes

Under these conditions, the DMA peripheral request controller issues the first DMA burst request when the SRAM fill level passes 128 bytes (the watermark level). The DMA peripheral request controller triggers consecutive DMA burst requests as long as there is sufficient data in the SRAM to perform burst type requests. In this example, DMA peripheral request controller can issue at least two consecutive DMA burst requests to transfer a total of 128 bytes. If there is sufficient data in the SRAM, the DMA peripheral request controller requests the third DMA burst immediately. Otherwise the DMA peripheral request controller waits for the SRAM fill level to pass the watermark level again to trigger the next burst request. When the watermark level is triggered, there is sufficient data in the SRAM to perform the third and fourth burst requests to complete the entire transaction.

For the indirect writes, the DMA peripheral request controller issues DMA requests immediately after the transfer is triggered and continues to do so until the entire indirect write transfer has been transferred. The rate at which DMA requests are issued depends on the watermark level. The `indwrwater` register defines the maximum fill level in bytes at which the controller can issue the first DMA burst or single request. When the SRAM fill level falls below the watermark level, the transfer watermark reached interrupt is generated. When there is one flash page of data in the SRAM, the quad SPI controller initiates the write operation from SRAM to the flash memory.

Software can disable the DMA peripheral request interface with the `endma` field of the `cfg` register. If a master other than the DMA performs the data transfer for indirect operations, the DMA peripheral request interface must be disabled. By default, the indirect watermark registers are set to zero, which means the DMA peripheral request controller can issue DMA request as soon as possible.

For more information about the HPS DMA controller, refer to the *DMA Controller* chapter in volume 3 of the Cyclone® V Device Handbook.

DMA Controller on page 16-1

Arbitration between Direct/Indirect Access Controller and STIG

When multiple controllers are active simultaneously, a fixed-priority arbitration scheme is used to arbitrate between each interface and access the external FLASH. The fixed priority is defined as follows, highest priority first.

1. The Indirect Access Write
2. The Direct Access Write
3. The STIG
4. The Direct Access Read
5. The Indirect Access Read

Each controller is back pressured while waiting to be serviced.

Configuring the Flash Device

For read and write accesses, software must initialize the device read instruction register (`devrd`) and the device write instruction register (`devwr`). These registers include fields to initialize the instruction opcodes that should be used as well as the instruction type, and whether the instruction uses single, dual or quad pins for address and data transfer. To ensure the quad SPI controller can operate from a reset state, the opcode registers reset to opcodes compatible with single I/O flash devices.

The quad SPI flash controller uses the instruction transfer width field (`instwidth`) of the `devrd` register to set the instruction transfer width for both reads and writes. There is no `instwidth` field in the `devwr` register. If instruction type is set to dual or quad mode, the address transfer width (`addrwidth`) and data transfer width (`datawidth`) fields of both registers are redundant because the address and data type is based on the instruction type. Thus, software can support the less common flash instructions where the opcode, address, and data are sent on two or four lanes. For most instructions, the opcodes are sent serially to the flash device, even for dual and quad instructions. One of the flash devices that supports instructions that can send the opcode over two or four lanes is the Micron N25Q128. For reference, Table 15-1 and Table 15-2 show how software should configure the quad SPI controller for each specific read and write instruction, respectively, supported by the Micron N25Q128 device.

Table 15-1: Quad SPI Configuration for Micron N25Q128 Device (Read Instructions)

Instruction	Lanes Used By Opcode	Lanes Used to Send Address	Lanes Used to Send Data	instwidth Value	addrwidth Value	datawidth Value
Read	1	1	1	0	0	0
Fast read	1	1	1	0	0	0
Dual output fast read (DOFR)	1	1	2	0	0	1
Dual I/O fast read (DIOFR)	1	2	2	0	1	1
Quad output fast read (QOFR)	1	1	4	0	0	2
Quad I/O fast read (QIOFR)	1	4	4	0	2	2
Dual command fast read (DCFR)	2	2	2	1	Don't care	Don't care
Quad command fast read (QCFR)	4	4	4	2	Don't care	Don't care

Table 15-2: Quad SPI Configuration for Micron N25Q128 Device (Write Instructions)

Instruction	Lanes Used By Opcode	Lanes Used to Send Address	Lanes Used to Send Data	instwidth Value	addrwidth Value	datawidth Value
Page program	1	1	1	0	0	0
Dual input fast program (DIFP)	1	1	2	0	0	1
Dual input extended fast program (DIEFP)	1	2	2	0	1	1
Quad input fast program (QIFP)	1	1	4	0	0	2
Quad input extended fast program (QIEFP)	1	4	4	0	2	2
Dual command fast program (DCFP)	2	2	2	1	Don’t care	Don’t care
Quad command fast program (QCFP)	4	4	4	2	Don’t care	Don’t care

XIP Mode

The quad SPI controller supports XIP mode, if the flash devices support XIP mode. Depending on the flash device, XIP mode puts the flash device in read-only mode, reducing command overhead.

The quad SPI controller must instruct the flash device to enter XIP mode by sending the mode bits. When the enter XIP mode on next read bit (`enterxipnextrd`) of the `cfg` register is set to 1, the quad SPI controller and the flash device are ready to enter XIP mode on the next read instruction. When the enter XIP mode immediately bit (`enterxipimm`) of the `cfg` register is set to 1, the quad SPI controller and flash device enter XIP mode immediately.

When the `enterxipnextrd` or `enterxipimm` bit of the `cfg` register is set to 0, the quad SPI controller and flash device exit XIP mode on the next read instruction. For more information, refer to the *“XIP Mode Operations”* section.

Related Information

XIP Mode Operations on page 15-17

Write Protection

You can program the controller to write protect a specific region of the flash device. The protected region is defined as a set of blocks, specified by a starting and ending block. Writing to an area of protected flash region memory generates an error and triggers an interrupt.

You define the block size by specifying the number of bytes per block through the number of bytes per block field (`bytespersubsector`) of the device size register (`devsz`). The lower write protection register (lowwrprot) specifies the first flash block in the protected region. The upper write protection register (uppwrprot) specifies the last flash block in the protected region.

The write protection enable bit (en) of the write protection register (wrprot) enables and disables write protection. The write protection inversion bit (inv) of the wrprot register flips the definition of protection so that the region specified by lowwrprt and uppwrprt is unprotected and all flash memory outside that region is protected.

Data Slave Sequential Access Detection

The quad SPI flash controller detects sequential accesses to the data slave interface by comparing the current access with the previous access. An access is sequential when it meets the following conditions:

- The address of the current access sequentially follows the address of the previous access.
- The direction of the current access (read or write) is the same as previous access.
- The size of the current access (byte, half-word, or word) is the same as previous access.

When the access is detected as nonsequential, the sequential access to the flash device is terminated and a new sequential access begins. Altera recommends accessing the data slave sequentially. Sequential access has less command overhead, and therefore, increases data throughput.

Clocks

There are two clock inputs to the quad SPI controller (l4_mp_clk and qspi_clk) and one clock output (sclk_out). The quad SPI flash controller uses the l4_mp_clk clock to clock the data slave transfers and register slave accesses. The qspi_clk clock is the reference clock for the quad SPI controller and is used to serialize the data and drive the external SPI interface. The sclk_out clock is the clock source for the connected flash devices.

The qspi_clk clock must be greater than two times the l4_mp_clk. The sclk_out clock is derived by dividing down the qspi_clk clock by the baud rate divisor field (bauddiv) of the cfg register.

Related Information

Clock Manager on page 2-1

Resets

A single reset signal (qspi_flash_rst_n) is provided as an input to the quad SPI controller. The reset manager drives the signal on a cold or warm reset.

Related Information

Reset Manager on page 3-1

Interrupts

All interrupt sources are combined to create a single level-sensitive, active-high interrupt (qspi_intr_in). Software can determine the source of the interrupt by reading the interrupt status register (irqstat). By default, the interrupt source is cleared when software writes a one (1) to the interrupt status register. The interrupts are individually maskable through the interrupt mask register (irqmask). Table 12–2 lists the interrupt sources in the irqstat register.

Table 15-3: Interrupt Sources in the irqstat Register

Interrupt Source	Description
Underflow detected	When 0, no underflow has been detected. When 1, the data slave write data is being supplied too slowly. This situation can occur when data slave write data is being supplied too slowly to keep up with the requested write operation This bit is reset only by a system reset and cleared only when a 1 is written to it.
Indirect operation complete	The controller has completed a triggered indirect operation.
Indirect read reject	An indirect operation was requested but could not be accepted because two indirect operations are already in the queue.
Protected area write attempt	A write to a protected area was attempted and rejected.
Illegal data slave access detected	An illegal data slave access has been detected. Data slave wrapping bursts and the use of split and retry accesses can cause this interrupt. It is usually an indicator that soft masters in the FPGA fabric are attempting to access the HPS in an unsupported way.
Transfer watermark reached	The indirect transfer watermark level has been reached.
Receive overflow	This condition occurs only in legacy SPI mode. When 0, no overflow has been detected. When 1, an over flow to the RX FIFO buffer has occurred. This bit is reset only by a system reset and cleared to zero only when this register is written to. If a new write to the RX FIFO buffer occurs at the same time as a register is read, this flag remains set to 1.
TX FIFO not full	This condition occurs only in legacy SPI mode. When 0, the TX FIFO buffer is full. When 1, the TX FIFO buffer is not full.
TX FIFO full	This condition occurs only in legacy SPI mode. When 0, the TX FIFO buffer is not full. When 1, the TX FIFO buffer is full.
RX FIFO not empty	This condition occurs only in legacy SPI mode. When 0, the RX FIFO buffer is empty. When 1, the RX FIFO buffer is not empty.

Interrupt Source	Description
RX FIFO full	This condition occurs only in legacy SPI mode. When 0, the RX FIFO buffer is not full. When 1, the RX FIFO buffer is full.
Indirect read partition overflow	Indirect Read Partition of SRAM is full and unable to immediately complete indirect operation

Interface Signals

The quad SPI controller provides four chip select outputs to allow control of up to four external quad SPI flash devices. The outputs serve different purposes depending on whether the device is used in single, dual, or quad operation mode. Table 12–3 lists the I/O pin use of the quad SPI controller interface signals for each operation mode.

Table 15-4: Interface Signals

Signal	Mode	Direction	Function
`data[0]`	Single	Output	Data output 0
	Dual or quad	Bidirectional	Data I/O 0
`data[1]`	Single	Input	Data input 0
	Dual or quad	Bidirectional	Data I/O 1
`data[2]`	Single or dual	Output	Active low write protect
	Quad	Bidirectional	Data I/O 2
`data[3]`	Single, dual, or quad	Bidirectional	Data I/O 3
`ss_n[0]`	Single, dual, or quad	Output	Active low slave select 0
`ss_n[1]`			Active low slave select 1
`ss_n[2]`			Active low slave select 2
`ss_n[3]`			Active low slave select 3
`sclk`			Serial clock

Quad SPI Flash Controller Programming Model

Setting Up the Quad SPI Flash Controller

The following steps describe how to set up the quad SPI controller:

1. Wait until any pending operation has completed.
2. Disable the quad SPI controller with the quad SPI enable field (`en`) of the `cfg` register.
3. Update the `instwidth` field of the `devrd` register with the instruction type you wish to use for indirect and direct writes and reads.
4. If mode bit enable bit (`enmodebits`) of the `devrd` register is enabled, update the mode bit register (`modebit`).
5. Update the `devsz` register as needed. Parts or all of this register might have been updated after initialization. The number of address bytes is a key configuration setting required for performing reads and writes. The number of bytes per page is required for performing any write. The number of bytes per device block is only required if the write protect feature is used.
6. Update the device delay register (`delay`). This register allows the user to adjust how the chip select is driven after each flash access. Each device may have different timing requirements. If the serial clock frequency is increased, these timing requirements become more critical. The numbers specified in this register are based on the period of the `qspi_clk` clock. For example, an some devices need 50 ns minimum time before the slave select can be reasserted after it has been deasserted. When the device is operating at 100 MHz, the clock period is 10 ns, so 40 ns extra is required. If the `qspi_clk` clock is running at 400 MHz (2.5 ns period), specify a value of at least 16 to the clock delay for chip select deassert field (`nss`) of the `delay` register.
7. Update the `remapaddr` register as needed. This register only affects direct access mode.
8. Set up and enable the write protection registers (`wrprot`, `lowwrprot`, and `uppwrprot`), when write protection is required.
9. Enable required interrupts though the `irqmask` register.
10. Set up the `bauddiv` field of the `cfg` register to define the required clock frequency of the target device.
11. Update the read data capture register (`rddatacap`) as needed. This register delays when the read data is captured and can help when the read data path from the device to the quad SPI controller is long and the device clock frequency is high.
12. Enable the quad SPI controller with the `en` field of the `cfg` register.

Indirect Read Operation with DMA Disabled

The following steps describe the general software flow to set up the quad SPI controller for indirect read operation with the DMA disabled:

1. Perform the steps described in the *"Setting Up the Quad SPI Flash Controller"* section.
2. Set the flash memory start address in the `indrdstaddr` register.
3. Set the number of bytes to be transferred in the `indrdcnt` register.
4. Set the indirect transfer trigger address in the `indaddrtrig` register.
5. Set up the required interrupts through the `irqmask` register.
6. If the watermark level is used, set the SRAM watermark level through the `indrdwater` register.
7. Start the indirect read operation by setting the `start` field of the `indrd` register to 1.

8. Either use the watermark level interrupt or poll the SRAM fill level in the `sramfill` register to determine when there is sufficient data in the SRAM.
9. Issue a read transaction to the indirect address to access the SRAM. Repeat **step 8** if more read transactions are needed to complete the indirect read transfer.
10. Either use the indirect complete interrupt to determine when the indirect read operation has completed or poll the completion status of the indirect read operation through the indirect completion status bit (`ind_ops_done_status`) of the `indrd` register.

Indirect Read Operation with DMA Enabled

The following steps describe the general software flow to set up the quad SPI controller for indirect read operation with the DMA enabled:

1. Perform the steps described in the *"Setting Up the Quad SPI Flash Controller"* section.
2. Set the flash memory start address in the `indrdstaddr` register.
3. Set the number of bytes to be transferred in the `indrdcnt` register.
4. Set the indirect transfer trigger address in the `indaddrtrig` register.
5. Set the number of bytes for single and burst type DMA transfers in the `dmaper` register.
6. Optionally set the SRAM watermark level in the `indrdwater` register to control the rate DMA requests are issued.
7. Start an indirect read access by setting the `start` field of the `indrd` register to 1.
8. Either use the indirect complete interrupt to determine when the indirect read operation has completed or poll the completion status of the indirect read operation through the `ind_ops_done_status` field of the `indrd` register.

Related Information

Setting Up the Quad SPI Flash Controller on page 15-15

Indirect Write Operation with DMA Disabled

The following steps describe the general software flow to set up the quad SPI controller for indirect write operation with the DMA disabled:

1. Perform the steps described in the *"Setting Up the Quad SPI Flash Controller"* section.
2. Set the flash memory start address in the `indwrstaddr` register.
3. Set up the number of bytes to be transferred in the `indwrcnt` register.
4. Set the indirect transfer trigger address in the `indaddrtrig` register.
5. Set up the required interrupts through the interrupt mask register (`irqmask`).
6. Optionally set the SRAM watermark level in the `indwrwater` register to control the rate DMA requests are issued. The value set must be greater than one flash page. For more information, refer to the *"Indirect Write Operation"* section.

7. Start the indirect write operation by setting the `start` field of the `indwr` register to 1.
8. Either use the watermark level interrupt or poll the SRAM fill level in the `sramfill` register to determine when there is sufficient space in the SRAM.
9. Issue a write transaction to the indirect address to write one flash page of data to the SRAM. Repeat **step 8** if more write transactions are needed to complete the indirect write transfer. The final write may be less than one page of data.

Indirect Write Operation with DMA Enabled

The following steps describe the general software flow to set up the quad SPI controller for indirect write operation with the DMA enabled:

1. Perform the steps described in the *"Setting Up the Quad SPI Flash Controller"* section.
2. Set the flash memory start address in the `indwrstaddr` register.
3. Set the number of bytes to be transferred in the `indcnt` field of the `indwr` register.
4. Set the indirect transfer trigger address in the `indaddrtrig` register.
5. Set the number of bytes for single and burst type DMA transfers in the `dmaper` register.
6. Optionally set the SRAM watermark level in the `indwrwater` register to control the rate DMA requests are issued. The value set must be greater than one flash page. For more information, refer to the *"Indirect Write Operation"* section.
7. Start the indirect write access by setting the `start` field of the `indirwr` register to 1.
8. Either use the indirect complete interrupt to determine when the indirect write operation has completed or poll the completion status of the indirect write operation through the `ind_ops_done_status` field of the `indwr` register.

XIP Mode Operations

XIP mode is supported in most SPI flash devices. However, flash device manufacturers do not use a consistent standard approach. Most use signature bits that are sent to the device immediately following the address bytes. Some devices use signature bits and also require a flash device configuration register write to enable XIP mode.

Entering XIP Mode

Micron Quad SPI Flash Devices with Support for Basic-XIP

To enter XIP mode in a Micron quad SPI flash device with support for Basic-XIP, perform the following steps:

1. Save the values in the mode bits, if you intend to restore them upon exit.
2. Disable the direct access controller and indirect access controller to ensure no new read or write accesses are sent to the flash device.
3. Set the XIP mode bits in the `modebit` register to 0x80.
4. Enable the quad SPI controller's XIP mode by setting the `enterxipnextrd` bit of the `cfg` register to 1.
5. Re-enable the direct access controller and, if required, the indirect access controller.

Micron Quad SPI Flash Devices without Support for Basic-XIP

To enter XIP mode in a Micron quad SPI flash device without support for Basic-XIP, perform the following steps:

1. Save the values in the mode bits, if you intend to restore them upon exit.
2. Disable the direct access controller and indirect access controller to ensure no new read or write accesses will be sent to the flash device.
3. Ensure XIP mode is enabled in the flash device by setting the volatile configuration register (VCR) bit 3 to 1. Use the `flashcmd` register to issue the VCR write command.
4. Set the XIP mode bits in the `modebit` register to 0x00.
5. Enable the quad SPI controller’s XIP mode by setting the `enterxipnextrd` bit of the `cfg` register to 1.
6. Re-enable the direct access controller and, if required, the indirect access controller.

Winbond Quad SPI Flash Devices

To enter XIP mode in a Winbond quad SPI flash device, perform the following steps:

1. Save the values in the mode bits, if you intend to restore them upon exit.
2. Disable the direct access controller and indirect access controller to ensure no new read or write accesses are sent to the flash device.
3. Set the XIP mode bits in the `modebit` register to 0x20.
4. Enable the quad SPI controller’s XIP mode by setting the `enterxipnextrd` bit of the `cfg` register to 1.
5. Re-enable the direct access controller and, if required, the indirect access controller.

Spansion Quad SPI Flash Devices

To enter XIP mode a Spansion quad SPI flash device, perform the following steps:

1. Save the values in the mode bits, if you intend to restore them upon exit.
2. Disable the direct access controller and indirect access controller to ensure no new read or write accesses are sent to the flash device.
3. Set the XIP mode bits in the `modebit` register to 0xA0.
4. Enable the quad SPI controller’s XIP mode by setting the `enterxipnextrd` bit of the `cfg` register to 1.
5. Re-enable the direct access controller and, if required, the indirect access controller.

Exiting XIP Mode

To exit XIP mode, perform the following steps:

1. Disable the direct access controller and indirect access controller to ensure no new read or write accesses are sent to the flash device.
2. Restore the mode bits to the values before entering XIP mode, depending on the flash device and manufacturer.
3. Set the `enterxipnextrd` bit of the `cfg` register to 0.

The flash device must receive a read instruction before it can disable its internal XIP mode state. Thus, XIP mode internally stays active until the next read instruction is serviced. Ensure that XIP mode is disabled before the end of any read sequence.

XIP Mode at Power on Reset

Some flash devices can be XIP-enabled as a nonvolatile configuration setting, allowing the flash device to enter XIP mode at power-on reset (POR) without software intervention. Software cannot discover the XIP state at POR through flash status register reads because an XIP-enabled flash device can only be accessed through the XIP read operation. If you known the device will enter XIP mode at POR, have your initial boot software configure the `modebit` register and set the `enterxipimm` bit of the `cfg` register to 1.

If you do not know in advance whether or not the device will enter XIP mode at POR, have your initial boot software issue an XIP mode exit command through the `flashcmd` register, then follow the steps in the *"Entering XIP Mode"* section. Software must be aware of the mode bit requirements of the device, because XIP mode entry and exit varies by device.

Related Information

Entering XIP Mode on page 15-18

FIFO RAM Initialization Requirement with ECC Enabled

Due to the Quad SPI controller FIFO implementation, a spurious ECC interrupt always happens when ECC is enabled for the first time. This happens because:

- The FIFO always reads from RAM when the write operation is not present
- The ECC syndrome bits generated when ECC is enabled only; and then remain uninitialized when ECC is disabled

Therefore, it reads the uninitialized content or syndrome bits when ECC is enabled for first time and generates the interrupt.

Note: If ECC is disabled, initialization is not required. However, if ECC is enabled after FIFO has been used for read or write operation, initialization must be done to initialize the ECC syndrome bits.

Clearing Spurious Interrupt

To clean this spurious interrupt, it is recommended for the driver or the system software to initialize the FIFO RAM and clear the interrupt for ECC usage.

1. Configure the SRAM Partition Register to maximize the FIFO RAM for read transfer.

The FIFO RAM is 512 bytes in size, which is 128 words for QSPI RAM. The recommended maximum read partition size is 126 words. This is the limitation support by SRAM Fill Level Register, which will leave 2 words for write partition.

2. Enable the ECC. This will trigger the spurious ECC interrupt.
3. Trigger an indirect read transfer with transfer size that will fill up the read partition, which is 126 words.
   Do not start the AHB read, this will ensure all read partition in FIFO RAM will be initialized. Monitor the SRAM Fill Level Register for the status.
4. Now start AHB read and start indirect write operation to write back to the same device location, this will fill up and initialized the write partition RAM.
5. To clear the spurious interrupt, the QSPI controller has to be reset then the QSPI ECC interrupt bit in system manager has to be cleared.

Quad SPI Flash Controller Address Map and Register Definitions

The address map and register definitions for the Quad SPI Flash Controller consist of the following regions:

- QSPI Flash Controller Module Registers
- QSPI Flash Module Data

Bit	Name	Description	Access	Reset
18	`enterxipimm`	If XIP is enabled, then setting to disabled will cause the controller to exit XIP mode on the next READ instruction. If XIP is disabled, then setting enable will operate the device in XIP mode immediately. Use this register when the external device wakes up in XIP mode (as per the contents of its non- volatile configuration register). The controller will assume the next READ instruction will be passed to the device as an XIP instruction, and therefore will not require the READ opcode to be transferred. Note: To exit XIP mode, this bit should be set to 0. This will take effect in the attached device only after the next READ instruction is executed. Software therefore should ensure that at least one READ instruction is requested after resetting this bit in order to be sure that XIP mode is exited. **Value** **Description** 0x1 Enter XIP Mode immediately 0x0 Exit XIP Mode on next READ instruction	`RW`	`0x0`
17	`enterxipnextrd`	If XIP is enabled, then setting to disabled will cause the controller to exit XIP mode on the next READ instruction. If XIP is disabled, then setting to enabled will inform the controller that the device is ready to enter XIP on the next READ instruction. The controller will therefore send the appropriate command sequence, including mode bits to cause the device to enter XIP mode. Use this register after the controller has ensured the FLASH device has been configured to be ready to enter XIP mode. Note : To exit XIP mode, this bit should be set to 0. This will take effect in the attached device only AFTER the next READ instruction is executed. Software should therefore ensure that at least one READ instruction is requested after resetting this bit before it can be sure XIP mode in the device is exited. **Value** **Description** 0x1 Enter XIP Mode on next READ instruction 0x0 Exit XIP Mode on next READ instruction	`RW`	`0x0`

irqstat Fields

Bit	Name	Description	Access	Reset
12	indsramfull	Indirect Read Partition of SRAM is full and unable to immediately complete indirect operation **Value** **Description** 0x1 SRAM is full 0x0 SRAM is not full	RW	0x0
11	rxfull	Indicates that the receive FIFO is full or not. Only relevant in SPI legacy mode. **Value** **Description** 0x0 Receive FIFO Not Full 0x1 Receive FIFO Full	RW	0x0
10	rxthreshcmp	Indicates the number of entries in the receive FIFO with respect to the threshold specified in the RXTHRESH register. Only relevant in SPI legacy mode. **Value** **Description** 0x0 FIFO has <= RXTHRESH entries 0x1 FIFO has > RXTHRESH entries	RW	0x0
9	txfull	Indicates that the transmit FIFO is full or not. Only relevant in SPI legacy mode. **Value** **Description** 0x0 Transmit FIFO Not Full 0x1 Transmit FIFO Full	RW	0x0

Bit	Name	Description	Access	Reset
8	`txthreshcmp`	Indicates the number of entries in the transmit FIFO with respect to the threshold specified in the TXTHRESH register. Only relevant in SPI legacy mode. **Value** — **Description** 0x0 — FIFO has > TXTHRESH entries 0x1 — FIFO has <= TXTHRESH entries	RW	0x1
7	`rxover`	This should only occur in Legacy SPI mode. Set if an attempt is made to push the RX FIFO when it is full. This bit is reset only by a system reset and cleared only when this register is read. If a new push to the RX FIFO occurs coincident with a register read this flag will remain set. 0 : no overflow has been detected. 1 : an overflow has occurred. **Value** — **Description** 0x1 — Receive Overflow 0x0 — No Receive Overflow	RW	0x0
6	`indxfrlvl`	Indirect Transfer Watermark Level Reached **Value** — **Description** 0x1 — Water level reached 0x0 — No water level reached	RW	0x0
5	`illegalacc`	Illegal AHB access has been detected. AHB wrapping bursts and the use of SPLIT/RETRY accesses will cause this error interrupt to trigger. **Value** — **Description** 0x1 — Illegal AHB attempt 0x0 — No Illegal AHB attempt	RW	0x0
4	`protwrattempt`	Write to protected area was attempted and rejected. **Value** — **Description** 0x1 — Write Attempt to protected area 0x0 — No Write Attempt	RW	0x0

Bit	Name	Description	Access	Reset
3	`indrdreject`	Indirect operation was requested but could not be accepted. Two indirect operations already in storage. **Value** / **Description** 0x1 Indirect Operation Requested 0x0 No Indirect Operation	RW	0x0
2	`indopdone`	Controller has completed last triggered indirect operation **Value** / **Description** 0x1 Completed Indirect Operation 0x0 No Indirect Operation	RW	0x0
1	`underflowdet`	An underflow is detected when an attempt to transfer data is made when the transmit FIFO is empty. This may occur when the AHB write data is being supplied too slowly to keep up with the requested write operation. This bit is reset only by a system reset and cleared only when the register is read. **Value** / **Description** 0x1 Underflow 0x0 No Underflow	RW	0x0

irqmask

If disabled, the interrupt for the corresponding interrupt status register bit is disabled. If enabled, the interrupt for the corresponding interrupt status register bit is enabled.

flashcmd Fields

Bit	Name	Description	Access	Reset
31:24	cmdopcode	The command opcode field should be setup before triggering the command. For example, 0x20 maps to SubSector Erase. Writeing to the execute field (bit 0) of this register launches the command. NOTE : Using this approach to issue commands to the device will make use of the instruction type of the device instruction configuration register. If this field is set to 2'b00, then the command opcode, command address, command dummy bytes and command data will all be transferred in a serial fashion. If this field is set to 2'b01, then the command opcode, command address, command dummy bytes and command data will all be transferred in parallel using DQ0 and DQ1 pins. If this field is set to 2'b10, then the command opcode, command address, command dummy bytes and command data will all be transferred in parallel using DQ0, DQ1, DQ2 and DQ3 pins.	RW	0x0
23	enrddata	If enabled, the command specified in the command opcode field (bits 31:24) requires read data bytes to be received from the device. **Value** **Description** 0x1 Command Requires read data 0x0 No Action	RW	0x0

DMA Controller 16

2014.07.31

cv_54016 Subscribe Send Feedback

This chapter describes the direct memory access controller (DMAC) contained in the hard processor system (HPS). The DMAC is used to transfer data between memory and peripherals and other memory locations in the system. The DMA controller is an instance of the ARM Corelink DMA Controller (DMA-330).

Related Information

http://infocenter.arm.com/

For more information about ARM's DMA-330 controller, refer to the *CoreLink DMA Controller DMA-330 Revision: r1p1* Technical Reference Manual on the ARM info center website

Features of the DMA Controller

The HPS provides one DMAC to handle the data transfer between memory-mapped peripherals and memories, off-loading this work from the microprocessor unit (MPU) subsystem. The DMAC supports memory-to-memory, memory-to-peripheral, and peripheral-to-memory transfers. The DMAC supports up to eight logical channels for different levels of service requirements. It provides up to 31 peripheral handshake interfaces for peripheral hardware flow control.

The DMA controller contains an instruction processing block that enables it to process program code that controls a DMA transfer. The DMAC also contains an ARM Advanced Microcontroller Bus Architecture (AMBA) Advanced eXtensible Interface (AXI) master interface unit to fetch the program code from system memory into its instruction cache. The AXI master interface also performs DMA data transfer as well. The DMA instruction execution engine executes the program code from its instruction cache and schedules read or write AXI instructions through the respective instruction queues. The DMAC also contains a multi-FIFO (MFIFO) data buffer that stores data that it reads, or writes, during a DMA transfer.

The DMAC provides 11 interrupt outputs to enable efficient communication of events to the MPU subsystem. The peripheral request interfaces support the connection of DMA-capable peripherals to enable memory-to-peripheral and peripheral-to-memory transfers to occur, without intervention from the processor. Because, the HPS supports some peripherals that do not comply with ARM DMA peripheral interface protocol, adapters are added to allow these peripherals to work with the DMAC.

The DMAC supports the following interface protocols:

- Synopsys protocol
    - Serial peripheral interface (SPI)
    - Universal asynchronous receiver/transmitter (UART)
    - Inter-integrated circuit (I^{2}C)
    - FPGA
- ARM protocol
    - Quad SPI flash controller
    - System trace macrocell (STM™)

Dual slave interfaces enable the operation of the DMA controller to be partitioned into the Secure state and Non-secure state. The network interconnect must be configured to ensure that only secure transactions can access the secure interface. The slave interfaces can access status registers and also directly execute instructions in the DMA controller.

The DMAC has the following features:

- A small instruction set that provides a flexible method of specifying the DMA operations. This architecture provides greater flexibility than the fixed capabilities of a Linked-List Item (LLI) based DMA controller.
- Supports multiple transfer types:
    - Memory-to-memory
    - Memory-to-peripheral
    - Peripheral-to-memory
    - Scatter-gather
- Supports up to eight DMA channels.
- Supports up to eight outstanding AXI read and eight outstanding AXI write transactions.
- Enables software to schedule up to 16 outstanding read and (16) outstanding write instructions.
- Supports (11) interrupt lines into the MPU subsystem:
    - One (1) for DMA thread abort
    - Eight (8) for events
    - Two (2) for MFIFO buffer ECC
- Single and double bit ECC support
- Supports 31 peripheral request interfaces:
    - Four (4) for FPGA
    - Four (4) shared for FPGA or Controller area network (CAN)
    - Eight (8) for I^{2}C
    - Eight (8) for SPI
    - Two (2) for quad SPI
    - One (1) for System Trace Macrocell (STM)
    - Four (4) for UART

DMA Controller Block Diagram and System Integration

The following figure shows a block diagram of the DMAC and how it integrates into the rest of the HPS system.

Level 4 Main Bus

The `l4_main_clk` clock drives the DMA controller, controller logic, and all the interfaces. The DMA controller accesses the level 3 (L3) main switch with its 64-bit AXI master interface.

The DMA controller provides the following slave interfaces:

- Non-secure slave interface
- Secure slave interface

You can use these slave interfaces to access the registers that control the functionality of the DMA controller. The DMA controller implements TrustZone secure technology with one interface operating in the Secure state and the other operating in the Non-secure state.

Functional Description of the DMA Controller

This section describes the major interfaces and components of the DMAC, and its operation.

The DMAC contains an instruction processing block that processes program code that controls a DMA transfer. The program code is stored in a region of system memory that the DMAC accesses using its AXI master interface. The DMAC stores instructions temporarily in an internal cache.

The DMAC has eight DMA channels. Each channel supports a single concurrent thread of DMA operation. In addition, a single DMA manager thread exists, and you can use it to initialize the DMA channel threads.

The DMAC executes up to one instruction per clock cycle. To ensure that it regularly executes each active thread, the DMAC alternates by processing the DMA manager thread and then a DMA channel thread. It performs a round-robin process when selecting the next active DMA channel thread to execute.

The DMAC uses variable-length instructions that consist of one to six bytes. It provides a separate program counter (PC) register for each DMA channel.

A 16-line instruction cache to improve the instruction fetch performance is implemented. Each line contains eight words (4 bytes each) making the cache line size 32 bytes. If you take the 32 bytes per cache line times the 16 cache lines, the instruction cache is equal to 512 bytes. When a thread requests an instruction from an address, the cache performs a lookup. If a cache hit occurs, then the cache immediately provides the instruction. Otherwise, the thread is stalled while the DMAC performs a cache line fill with the AXI master interface. If an instruction spans the end of a cache line, the DMAC performs multiple cache accesses to fetch the instruction.

Note: When a cache line fill is in progress, the DMAC enables other threads to access the cache. But if another cache miss occurs, the pipeline stalls until the first line fill is complete.

When a DMA channel thread executes a load or store instruction, the DMAC adds the instruction to the relevant read or write queue. The DMAC uses these queues as an instruction storage buffer prior to it issuing the instructions on the AXI. The DMAC also contains an MFIFO data buffer in which it stores data that it reads, or writes, during a DMA transfer.

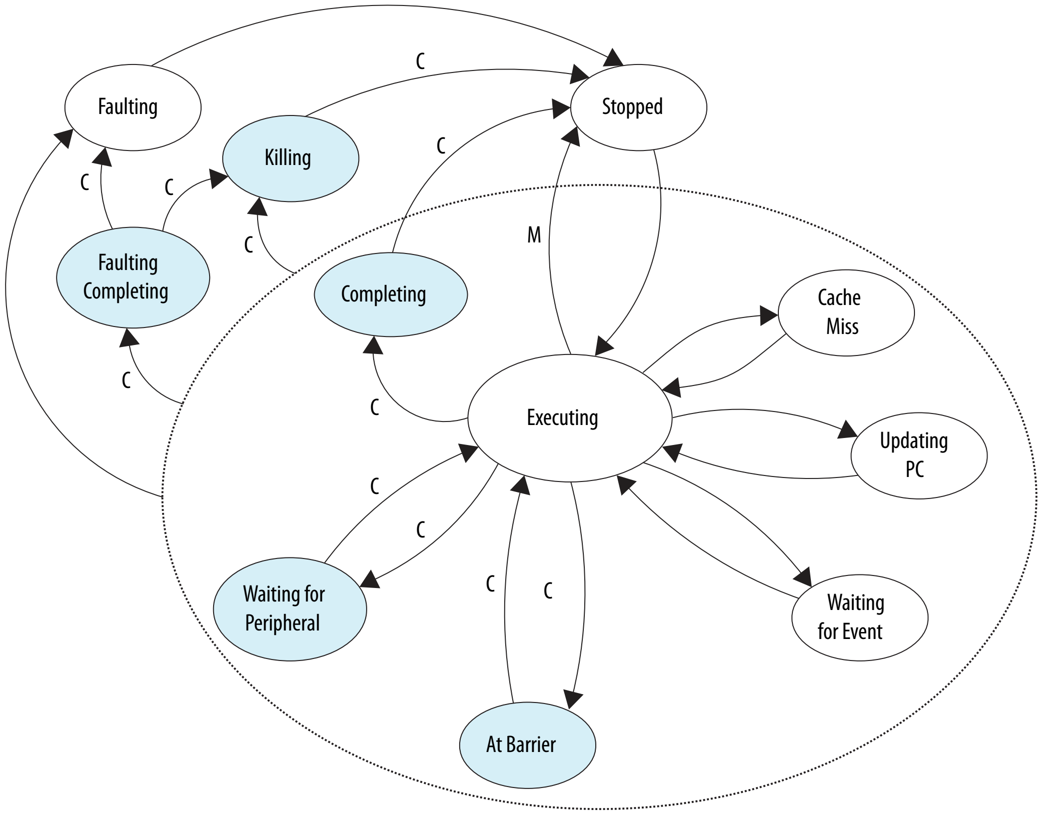
The DMAC provides multiple interrupt outputs to enable efficient communication of events to external microprocessors. The peripheral request interfaces support the connection of DMA-capable peripherals to enable memory-to-peripheral and peripheral-to-memory DMA transfers to occur, without intervention from a microprocessor.

Dual slave interfaces enable the operation of the DMAC to be partitioned into the Secure state and Non-secure states. You can access status registers and also directly execute instructions in the DMAC with the slave interfaces.

Operating States

The following figure shows the transitions among operating states for the DMA manager thread and DMA channel threads. The DMAC provides a separate state machine for each thread.

Figure 16-2: Thread Operating States



In the above figure, the DMAC permits all of the following:

- Only DMA channel threads can use states shown in blue
- Arcs with no letter designator indicate state transitions for the DMA manager and DMA channel threads, otherwise use is restricted as follows:
  - C—DMA channel threads only
  - M—DMA manager thread only
- States within the dotted line can transition to the Faulting completing, Faulting, or Killing

After the DMAC exits from reset, it sets all DMA channel threads to the Stopped state, and DMA manager thread moves to the Stopped state.

The following sections describe the *Thread Operating* states:

Stopped

The thread has an invalid PC (Program Counter) and it is not fetching instructions. Depending on the thread type, you can cause the thread to move to the Executing state by all of the following:

- DMA manager thread—Issuing the DMAGO instruction through the slave interface
- DMA channel thread—Programming the DMA manager thread to execute `DMAGO` for a DMA channel thread in the Stopped state

Executing

The thread has a valid PC and therefore the DMAC includes the thread when it arbitrates. The thread can then change to one of the following states under the following conditions:

- Stopped—When the DMA manager thread executes `DMAEND`
- Cache miss—When the instruction cache does not contain the next instruction for either the DMA manager thread or the DMA channel thread
- Updating PC—When the DMAC calculates the address of the next access in the cache
- Waiting for event—When a thread executes `DMAWFE`
- At barrier—When a DMA channel thread either:
  - Executes `DMARMB`, `DMAWMB`, or `DMAFLUSHP`
  - Updates control registers that affect alignment during a DMA Cycle
- Waiting for peripheral—When a DMA channel thread executes `DMAWFP`
- Killing—When a DMA channel thread executes `DMAKILL`
- Faulting completing—For a DMA channel thread when either:
  - The thread executes an undefined or invalid instruction
  - An AXI error occurs during an instruction fetch or data transfer
- Faulting—For the DMA manager thread when either:
  - The thread executes an undefined or invalid instruction
  - An AXI error occurs during an instruction fetch

  For a DMA channel thread when a watchdog timeout abort occurs.
- Completing—When a DMA channel thread executes `DMAEND`

Cache Miss

The thread is stalled and the DMAC is performing a cache line fill. After it completes the cache fill, the thread returns to the Executing state.

Updating PC

The DMAC is calculating the address of the next access in the cache. After it calculates the PC, the thread returns to the Executing state.

Waiting For Event

The thread is stalled and is waiting for the DMAC to execute `DMASEV` using the corresponding event number. After the corresponding event occurs, the thread returns to the Executing state.

At Barrier

A DMA channel thread is stalled and the DMAC is waiting for transactions on the AXI to complete. After the AXI transactions complete, the thread returns to the Executing state.

Waiting For Peripheral

A DMA channel thread is stalled and the DMAC is waiting for the peripheral to provide the requested data. After the peripheral provides the data, the thread returns to the Executing state.

Faulting Completing

A DMA channel thread is waiting for the AXI master interface to signal that the outstanding load or store transactions are complete. After the transactions complete, the thread moves to the Faulting state.

Faulting

The thread is stalled indefinitely. The thread moves to the Stopped state when you use the DBGCMD register to instruct the DMAC to execute DMAKILL for that thread.

Killing

A DMA channel thread is waiting for the AXI master interface to signal that the outstanding load or store transactions are complete. After the transactions complete, the thread moves to the Stopped state.

Completing

A DMA channel thread is waiting for the AXI master interface to signal that the outstanding load or store transactions are complete. After the transactions complete, the thread moves to the Stopped state.

Related Information

Updating DMA Channel Control Registers During a DMA Cycle on page 16-24

Initializing the DMAC

The DMAC provides several memory-mapped control signals that initialize its operating state when it exits from reset. The DMAC does not automatically begin executing code when it exits from reset. The system manager controls these memory-mapped control signals.

Related Information

System Manager on page 5-1

How to Set the Security State of the DMA Manager

The boot_manager_ns signal is the only method to set the security state of the DMA manager.

When the DMAC exits from reset, it reads the status of the boot_manager_ns signal and sets the security of the DMA manager.

Note: When set, the security state remains constant until a state transition on the dma_rst_n signal resets the DMAC.

Related Information

- DMA Manager Thread in Secure State on page 16-20
  Describes how the security state of the DMA manager affects how the DMAC operates.
- DMA Manager Thread in Non-Secure State on page 16-20

How to Set the Security State for the Interrupt Outputs

The DMAC provides the boot_irq_ns[7:0] signals to enable you to assign each irq[x] signal to a security state.

The boot_irq_ns[7:0] signals connect to the system manager. Before taking the DMA out of reset, you should program boot_irq_ns[7:0] through the system manager to control which interrupt bits are secure.

Note: The DMAC samples the `boot_irq_ns[7:0]` bits immediately after it comes out of reset, and then ignores them until the next reset.

When set, the security state of each `irq[x]` signal remains constant until a state transition on the `dma_rst_n` signal resets the DMAC.

Related Information

Security Usage on page 16-19
Describes how the security state of the irq[x] signals affects how the DMAC executes the DMAWFE and DMASEV instructions.

How to Set the Security State for a Peripheral Request Interface

The DMAC provides the signals to enable you to assign each peripheral request interface to a security state.

The `boot_periph_ns[31:0]` signals connect to the system manager. Before taking the DMA out of reset, you should program the `boot_periph_ns[31:0]` signals through the system manager to control which peripheral interfaces are secure.

Note: The DMAC samples the `boot_periph_ns[31:0]` bits immediately after it comes out of reset, and then ignores them until the next reset. When set, the security state of each peripheral request interface remains constant, until a state transition on the `dma_rst_n` signal resets the DMAC.

Related Information

Security Usage on page 16-19
Describes the effect of the security state of the peripheral request interfaces on the execution of the DMAWFP, DMALDP, DMASTP, or DMAFLUSHP instructions by a DMA channel thread.

Using the Slave Interfaces

The slave interfaces connect the DMAC to the level 4 (L4) main bus and enable a microprocessor to access the registers. Using these registers, a microprocessor can perform the following functions:

- Access the status of the DMA manager thread
- Access the status of the DMA channel threads
- Enable or clear interrupts
- Enable events
- Execute an instruction for the DMAC by programming the following debug registers:
    - `DBGCMD` register
    - `DBGINST0` register
    - `DBGINST1` register

Issuing Instructions to the DMAC using a Slave Interface

When the DMAC is operating, you can only issue the following instructions:

- `DMAGO`—Starts a DMA transaction using a DMA channel that you specify
- `DMASEV`—Signals the occurrence of an event, or interrupt, using an event number that you specify
- `DMAKILL`—Terminates a thread

You must ensure that you use the appropriate slave interface, depending on the security state in which the `boot_manager_ns` signal initializes the DMAC. For example, if the DMAC is in the Secure state, you must issue the instruction using the secure slave interface, otherwise the DMAC ignores the instruction. You can use the secure or non-secure slave interface to start or restart a DMA channel when the DMAC is in the Non-secure state.

Note: Before you can issue instructions using the debug instruction registers or the DBGCMD register, you must read the DBGSTATUS register to ensure that debug is idle, otherwise the DMAC ignores the instructions.

The DMAC immediately processes any instructions received from a slave interface, unless the pipeline is busy processing another instruction.

Note: Prior to issuing DMAGO, you must ensure that the system memory contains a suitable program for the DMAC to execute, starting at the address that the DMAGO specifies.

Using DMAGO with the Debug Instruction Registers

The following example shows the necessary steps to start a DMA channel thread using the debug instruction registers:

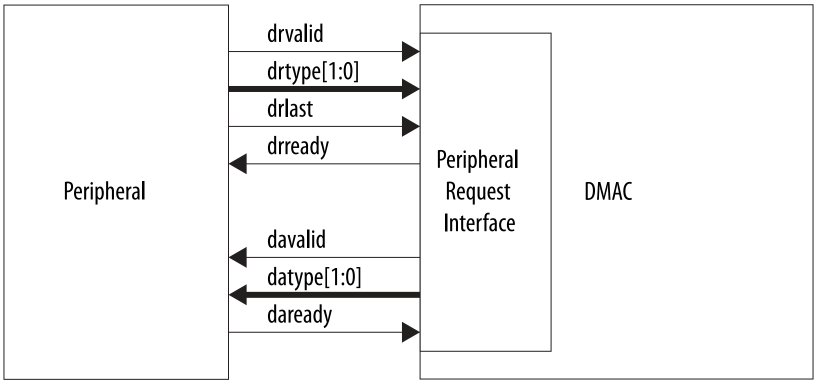
1. Create a program for the DMA channel.
2. Store the program in a region of system memory.
3. Program one of the slave interfaces on the DMAC to a DMAGO instruction as follows:
   a. Poll the DBGSTATUS register to ensure that debug is idle, and the dbgstatus bit is 0.
   b. Write to the DBGINST0 register and enter all of the following:
      - Instruction byte 0 encoding for DMAGO
      - Instruction byte 1 encoding for DMAGO
      - Debug thread bit to 0 to select the DMA manager thread
   c. Write to the DBGINST1 register with the DMAGO instruction byte [5:2] data. You must set these four bytes to the address of the first instruction in the program, that is written to system memory in step 2 above.
4. Instruct the DMAC to execute the instruction that the debug instruction registers contain by writing zero to the DBGCMD register. The DMAC starts the DMA channel thread and sets the dbgstatus bit to 1. After the DMAC completes execution of the instruction, it clears the dbgstatus bit to 0.

Peripheral Request Interface

The following figure shows that the peripheral request interface consists of a peripheral request bus and a DMAC acknowledge bus that use the prefixes:

- dr—The peripheral request bus
- da—The DMAC acknowledge bus

Figure 16-3: Request and Acknowledge Buses on the Peripheral Request Interface



The peripheral indicates the following on the request bus:

- Request a single transfer
- Request a burst transfer
- Acknowledge a flush request

The peripheral indicates the DMAC when it issues the last request of the DMA transfer sequence.

The DMAC can indicate the following on the acknowledge bus:

- When it completes the requested single transfer
- When it completes the requested burst transfer
- When it issues a flush request

You can assign a peripheral request interface to any of the DMA channels. When a DMA channel thread executes `DMAWFP`, the value programmed in the peripheral [4:0] field specifies the peripheral associated with that DMA channel.

The DMAC supports 31 peripheral request handshakes. Each request handshake can receive up to four outstanding requests, and is assigned a specific peripheral device ID. The following table lists the peripheral device ID assignments.

Table 16-1: Peripheral Request Interface Mapping

Peripheral	Request Interface ID	Protocol	Peripheral	Request Interface ID	Protocol
FPGA 0	0	Synopsys	SPI Master 0 TX	16	Synopsys
FPGA 1	1	Synopsys	SPI Master 0 RX	17	Synopsys
FPGA 2	2	Synopsys	SPI Slave 0 TX	18	Synopsys
FPGA 3	3	Synopsys	SPI Slave 0 RX	19	Synopsys

FPGA 4 /CAN 0 interface 1	4	Synopsys / Bosch	SPI Master 1 TX	20	Synopsys
FPGA 5 /CAN 0 interface 2	5	Synopsys / Bosch	SPI Master 1 RX	21	Synopsys
FPGA 6 /CAN 1 interface 1	6	Synopsys / Bosch	SPI Slave 1 TX	22	Synopsys
FPGA 7 /CAN 1 interface 2	7	Synopsys / Bosch	SPI Slave 1 RX	23	Synopsys
I^{2}C 0 TX	8	Synopsys	Quad SPI Flash TX	24	ARM
I^{2}C 0 RX	9	Synopsys	Quad SPI Flash RX	25	ARM
I^{2}C 1 TX	10	Synopsys	STM	26	ARM
I^{2}C 1 RX	11	Synopsys	Reserved	27	Synopsys
I^{2}C 2 TX (EMAC)	12	Synopsys	UART 0 TX	28	Synopsys
I^{2}C 2 RX (EMAC)	13	Synopsys	UART 0 RX	29	Synopsys
I^{2}C 3 TX (EMAC)	14	Synopsys	UART 1 TX	30	Synopsys
I^{2}C 3 RX (EMAC)	15	Synopsys	UART 1 RX	31	Synopsys

Note: Request interface numbers 4 through 7 are multiplexed between the CAN controllers and soft logic implemented in the FPGA fabric. The switching between the CAN controller and FPGA interfaces is controlled by the system manager.

Request Acceptance Capability

The DMAC can accept one active request for each peripheral request interface. An active request exists when the DMAC has not started the requested AXI data transfers.

Peripheral Length Management

A peripheral can control the quantity of data that a DMA cycle contains, without the DMAC being aware of how many data transfers it contains. The peripheral controls the DMA cycle in one of the following ways:

- Selects a single transfer
- Selects a burst transfer
- Notifies the DMAC when it commences the final request in the current series

When the DMAC executes a DMAWFP peripheral instruction, it halts execution of the thread and waits for the peripheral to send a request. When the peripheral sends the request, the DMAC sets the request flags depending on the state of the following signals:

- drtype_<x>[1:0] —The DMAC sets the state of the request_type flag:
  - drtype_<x>[1:0]=b00—request_type <x> = Single
  - drtype_<x>[1:0]=b01—request_type <x> = Burst
- drlast_<x>—The DMAC sets the state of the request_last flag:
  - drlast_<x>=0—request_last <x> = 0
  - drlast_<x>=1—request_last <x> = 1

Note: If the DMAC executes a DMAWFP single or DMAWFP burst instruction then the DMAC sets:

- The request_type<x> flag to Single or Burst, respectively
- The request_last<x> flag to 0

DMALPFE is an assembler directive which forces the associated DMALPEND instruction to have its nf bit set to 0. This creates a program loop that does not use a loop counter to terminate the loop.

The DMAC exits the loop when the request_last flag is set to 1.

The DMAC conditionally executes the following instructions, depending on the state of the request_type and request_last flags:

- DMALD , DMAST , DMALPEND

When these instructions use the optional B|S suffix then the DMAC executes a DMANOP if the request_type flag does not match.

- DMALDP<B|S> , DMASTP<B|S>

The DMAC executes a DMANOP if the request_type <x> flag does not match the B|S

- DMALPEND

When the nf bit is 0, the DMAC executes a DMANOP if the request_last flag is set.

Use the DMALDB, DMALDPB, DMASTB and DMASTPB instructions if you require the DMAC to issue a burst transfer when the DMAC receives a burst request. The values in the CCR *n* register control the amount of data that the DMAC transfers.

Use the DMALDS, DMALDPS, DMASTS and DMASTPS instructions if you require the DMAC to issue a single transfer when the DMAC receives a single request. The DMAC ignores the value of the src_burst_len and dst_burst_len fields in the CCR*n* register and sets the arlen[3:0] or awlen[3:0] buses to 0x0.

DMAC Length Management

The DMAC controls the total amount of data. The peripheral uses the peripheral request interface to notify the DMAC when it requires the DMAC to transfer data to or from the peripheral. The DMA channel thread controls how the DMAC responds to the peripheral requests.

The following constraints apply to DMAC length management:

- The total quantity of data for all the single requests from a peripheral must be less than the quantity of data for a burst request for that peripheral.

  Note: The `CCRn` register controls how much data is transferred for a burst request and a single request. Altera recommends that you do not update a `CCRn` register when a transfer is in progress for channel `n`.

- After the peripheral sends a burst request, the peripheral must not send a single request until the DMAC acknowledges that the burst request is complete.

Program the `DMAWFP` single instruction when you require the program thread to halt execution until the peripheral request interface receives any request type.

- Single— If the head entry in the request FIFO buffer is a single request type, the DMAC pops the entry from the FIFO buffer and continues program execution.
- Burst—If the head entry in the request FIFO buffer is a burst request type, the DMAC leaves the entry in the FIFO buffer and continues program execution.

  Note: The burst request entry remains in the request FIFO buffer until the DMAC executes a `DMAWFP` burst instruction or a `DMAFLUSHP` instruction.

Program the `DMAWFP` burst instruction when you require the program thread to halt execution until the peripheral request interface receives a burst request.

- Single—If the head entry in the request FIFO buffer is a single request type, the DMAC removes the entry from the FIFO buffer and continues program execution.
- Burst—If the head entry in the request FIFO buffer is a burst request type, the DMAC pops the entry from the FIFO buffer and continues program execution.

Program the `DMALDP` instruction when you require the DMAC to send an acknowledgment to the peripheral when it completes the AXI read transfers. Similarly, use the `DMASTP` instruction when you require the DMAC to send an acknowledgment to the peripheral when it completes the AXI write transfers. The DMAC uses the acknowledge bus to signal a transfer acknowledgment to peripheral <x>.

Note: The DMAC sends an acknowledgment for a read transaction when the `rvalid` and `rlast` signals are high and for a write transaction when `bvalid` signal is high. The DMAC might send an acknowledgment to the peripheral while the transfer of write data to the end destination is still in progress.

Use the `DMAFLUSHP` instruction to reset the request FIFO buffer for the peripheral request interface. After the DMAC executes `DMAFLUSHP`, it ignores peripheral requests until the peripheral acknowledges the flush request. This enables the DMAC and peripheral to synchronize with each other.

ARM Protocol

The DMA peripheral request interface communicates with peripherals by either the ARM protocol or the Synopsys protocol.

For peripherals using the ARM protocol, clock-crossing logic is the only logic between the DMA and the peripheral.

Synopsys Protocol Overview

The FIFO is Avalon®-MM based with hardware flow control that is compatible with the DMA-330 core in the HPS. The Synopsys protocol is used for the hardware flow control which is not the same as the ARM® protocol used by the DMA-330 core.

For peripherals using the Synopsys protocol, clock-crossing logic and protocol adaptation logic exist between the DMA and the peripheral.

The Synopsys protocol is described, below:

- A single transfer line is asserted whenever the peripheral is able to accept a single word transfer.
- A burst transfer line is asserted when the peripheral is able to accept a burst transfer. The burst transfer size needs to be identically set in both the DMA and peripheral to avoid potential data loss or corruption.
- The single and burst transfer lines must remain asserted until the DMA issues an acknowledge back to the peripheral.

  Note: If the peripheral needs to be reset, then the DMA should be instructed to flush the request which will be translated into an acknowledgement by the Synopsys protocol adapter.
- When a transfer is acknowledged the peripheral must deassert the burst and single request lines for the duration of the acknowledgment.

Note: A transmit or receive request is not complete until the DMA issues an acknowledge back to the peripheral.

Using Events and Interrupts

The DMAC can support eight events and interrupts. The `INTEN` register determines whether each event-interrupt resource is an event or an interrupt.

When the DMAC executes a `DMASEV` instruction it modifies the event-interrupt resource that you specify. The `INTEN` register sets the event-interrupt resource to function as an:

- **Event**—The DMAC generates an event for the specified event-interrupt resource. When the DMAC executes a `DMAWFE` instruction for the same event-interrupt resource then it clears the event.
- **Interrupt**—The DMAC sets the `irq <event_num>` signal high, where <event_num> is the number of the specified event resource. To clear the interrupt you must write to the `INTCLR` register.

Using an Event to Restart DMA Channels

When you program the `INTEN` register to generate an event, you can use the `DMASEV` and `DMAWFE` instructions to restart one or more DMA channels.

DMAC executes DMAWFE before DMASEV

To restart a single DMA channel:

1. The first DMA channel executes `DMAWFE` and then stalls while it waits for the event to occur.
2. The other DMA channel executes `DMASEV` using the same event number. This generates an event, and the first DMA channel restarts. The DMAC clears the event, one clock cycle after it executes `DMASEV`.

You can program multiple channels to wait for the same event. For example, if four DMA channels have all executed DMAWFE for event 2, and another DMA channel executes DMASEV for event 2, the four DMA channels all restart at the same time. The DMAC clears the event, one clock cycle after it executes DMASEV.

DMAC executes DMASEV before DMAWFE

If the DMAC executes DMASEV before another channel executes DMAWFE, the event remains pending until the DMAC executes DMAWFE. When the DMAC executes DMAWFE, it halts execution for one aclk clock cycle, clears the event and then continues execution of the channel thread.

For example, if the DMAC executes DMASEV 6 and none of the other threads have executed DMAWFE 6, then the event remains pending. If the DMAC executes the DMAWFE 6 instruction for channel 4 and then executes the DMAWFE 6 instruction for channel 3, the following actions occur:

1. The DMAC halts execution of the channel 4 thread for one clock cycle.
2. The DMAC clears event 6.
3. The DMAC resumes execution of the channel 4 thread.
4. The DMAC halts execution of the channel 3 thread and the thread stalls while it waits for the next occurrence of event 6.

Interrupting the MPU Subsystem

The DMAC provides the irq[x] signals for use as active-high level-sensitive interrupts to the MPU subsystem. When you program the INTEN register to generate an interrupt, after the DMAC executes DMASEV, it sets the corresponding irq[x] signal high.

The MPU subsystem can clear the interrupt by writing to the INTCLR register.

Note: Executing DMAWFE does not clear an interrupt.

If you use the DMASEV instruction to notify a microprocessor when the DMAC completes a DMALD or DMAST instruction then you should insert a memory barrier instruction before the DMASEV. Otherwise the DMAC might signal an interrupt before the AXI transfers complete.

The following program shows the example of Memory Barrier Instruction.

```
DMALD
DMAST
# Issue a write memory barrier
# Wait for the AXI write transfer to complete before the DMAC
# can send an interrupt
DMAWMB
# The DMAC sends the interrupt
DMASEV
```

Aborts

Abort Types

An abort can be classified as either precise or imprecise, depending on whether the DMAC provides an abort handler with the precise state of the DMAC when the abort occurs.

- **Precise Abort**: The DMAC updates the PC register with the address of the instruction that created the abort.
- **Imprecise Abort**: The PC register might contain the address of an instruction which did not cause the abort to occur.

Abort Sources

The DMAC indicates a precise abort under any of the following conditions:

- A DMA channel thread in the Non-secure state attempts to program its `CCRn` register and generate a secure AXI transaction.
- A DMA channel thread in the Non-secure state executes `DMAWFE` or `DMASEV` for an event that is set as secure. The `boot_irq_ns` memory-mapped control signals initialize the security state for an event.

Note: For each event, the INTEN register controls if the DMAC generates an event or signals an interrupt.

- A DMA channel thread attempts to execute `DMAST` but the DMAC calculates that when it eventually performs the store, the MFIFO buffer contains insufficient data to enable it to complete the store.
- A DMA channel thread in the Non-secure state executes `DMAWFP`, `DMALDP`, `DMASTP`, or `DMAFLUSHP` for a peripheral request interface that is set as secure. The `boot_periph_ns` memory-mapped control signals initialize the security state for a peripheral request interface.
- A DMA manager thread in the Non-secure state executes `DMAGO` to attempt to start a secure DMA channel thread.
- The DMAC receives an ERROR response on the AXI master interface when it performs an instruction fetch.
- A thread executes an undefined instruction.
- A thread executes an instruction with an operand that is invalid for the configuration of the DMAC.

Note: When the DMAC signals a precise abort, the instruction that triggers the abort is not executed. Instead, the DMAC executes a `DMANOP`.

The DMAC signals an imprecise abort under the following conditions:

- The DMAC receives an ERROR response on the AXI master interface when it performs a data load.
- The DMAC receives an ERROR response on the AXI master interface when it performs a data store.
- A DMA channel thread executes `DMALD` or `DMAST`, and the MFIFO buffer is too small to hold the required amount of data.
- A DMA channel thread executes `DMAST` but the thread has not executed sufficient `DMALD` instructions.
- A DMA channel thread locks up because of resource starvation, and this causes the internal watchdog timer to time out.

Watchdog Abort

The DMAC can lock up if one or more DMA channel programs are running and the MFIFO buffer is too small to satisfy the storage requirements of the DMA programs.

The DMAC contains logic to prevent it from remaining in a state where it is unable to complete a DMA transfer.

The DMAC detects a lock up when all of the following conditions occur:

- Load queue is empty.
- Store queue is empty.
- All of the running channels are prevented from executing a `DMALD` instruction either because the MFIFO buffer does not have sufficient free space or another channel owns the load-lock.

When the DMAC detects a lockup, it signals an interrupt and can also abort the contributing channels. The DMAC behavior depends on the state of the wd_irq_only bit in the WD register, if:

- wd_irq_only=0—The DMAC aborts all of the contributing DMA channels and sets the irq_abort signal high.
- wd_irq_only=1—The DMAC sets the irq_abort signal high.

Related Information

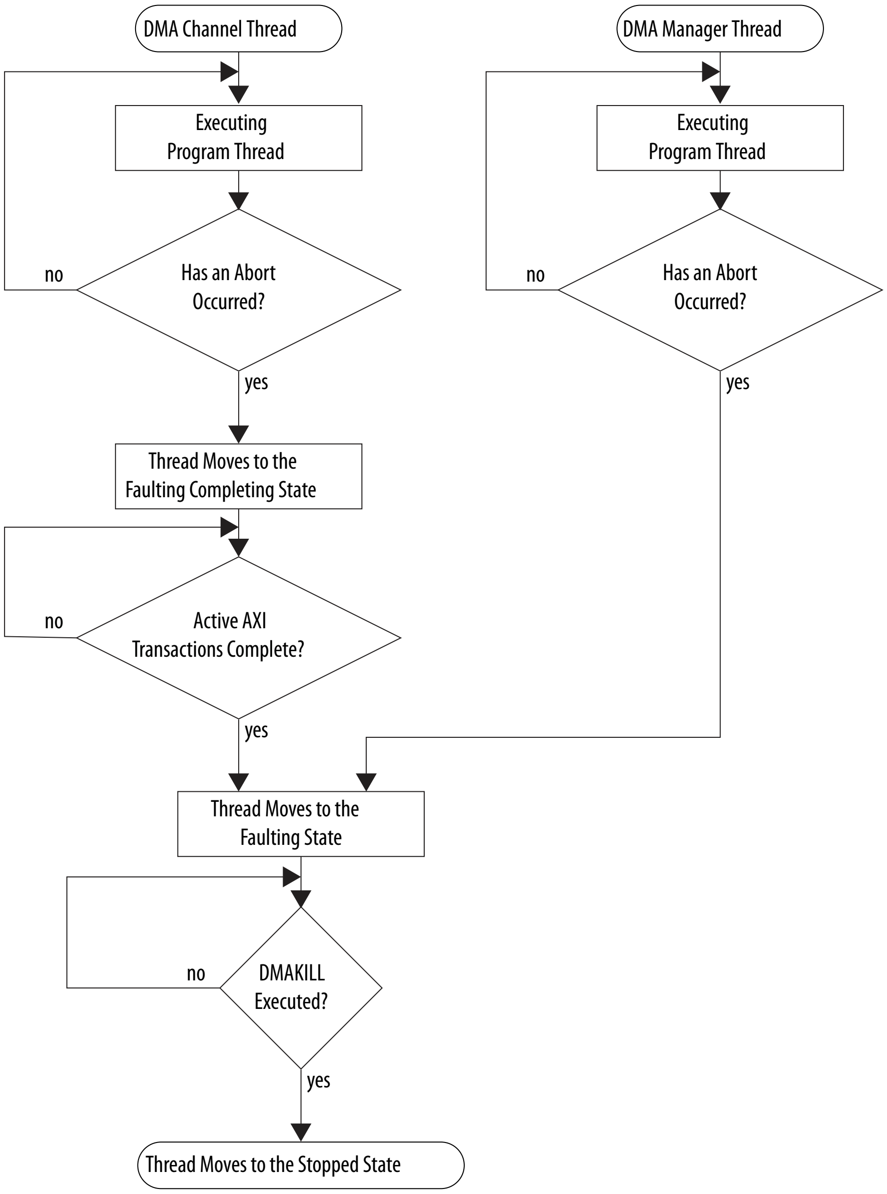
Resource Sharing Between DMA Channels on page 16-24

Abort Handling

The architecture of the DMAC is not designed to recover from an abort. You must use an external agent, such as a microprocessor, to terminate a thread when an abort occurs.

The following figure shows the operating states for the DMA channel and DMA manager threads after an abort occurs.

Figure 16-4: Abort Process



After an abort occurs, the action of the DMAC depends on the thread type:

- DMA channel thread—The thread immediately moves to the Faulting completing state. In this state, the DMAC performs the following operations:
  - Sets the `irq_abort` signal high.
  - Stops executing instructions for the DMA channel.
  - Invalidates all cache entries for the DMA channel updates the `CPC` *n* register to contain the address of the aborted instruction provided that the abort is precise.
  - Does not generate AXI accesses for any instructions remaining in the read queue and write queue.
  - Permits currently active AXI transactions to complete.

  Note: After the transactions for the DMA channel finish, the thread moves to the Faulting state.
- DMA manager thread—The thread immediately moves to the Faulting state and the DMAC sets the `irq_abort` signal high.

  The external agent can respond to the assertion of the `irq_abort` signal by all of the following:
  - Reading the status of the `FSRD` register to determine if the DMA manager is Faulting. In the Faulting state, the `FSRD` register provides the cause of the abort.
  - Reading the status of the `FSRC` register to determine if a DMA channel is Faulting. In the Faulting state, the `FSRC` register provides the cause of the abort.

  To enable a thread in the Faulting state to move to the Stopped state, the external agent must:
  - Program the `DBGINST0` register with the encoding for the `DMAKILL` instruction.
  - Write to the `DBGCMD` register.

  Note: If the aborted thread is secure, you must use the secure slave interface to update these registers.

  After a thread in the Faulting state executes `DMAKILL`, it moves to the Stopped state.

Security Usage

When the DMAC exits from reset, the status of the configuration signals configures the security for:

- DMA manager thread—The `DNS` bit in the DSR register returns the security state of the DMA manager thread.
- Events and interrupts—The `INS` bit in the `CR3` register returns the security state of the event-interrupt resources.
- Peripheral request interfaces—The `PNS` bit in the `CR4` register returns the security state of these interfaces.

Additionally, each DMA channel thread contains a dynamic non-secure bit, `CNS`, that is valid when the channel is not in the Stopped state.

DMA Manager Thread in Secure State

If the DNS bit is 0, the DMA manager thread operates in the Secure state and performs only secure instruction fetches. When a DMA manager thread in the Secure state processes:

- DMAGO—The DMAC uses the status of the ns bit, to set the security state of the DMA channel thread by writing to the CNS bit for that channel.
- DMAWFE—The DMAC halts execution of the thread until the event occurs. When the event occurs, the DMAC continues execution of the thread, irrespective of the security state of the corresponding INS bit.
- DMASEV—The DMAC sets the corresponding bit in the INT_EVENT_RIS register, irrespective of the security state of the corresponding INS bit.

DMA Manager Thread in Non-Secure State

If the DNS bit is 1, the DMA manager thread operates in the Non-secure state, and it only performs non-secure instruction fetches. When a DMA manager thread in the Non-secure state processes:

- DMAGO—The DMAC uses the status of the ns bit, to control if it starts a DMA channel thread.
  - If ns = 0—The DMAC does not start a DMA channel thread and instead it:
    - Executes an NOP.
    - Sets the FSRD register.
    - Sets the dmago_err bit in the FTRD register.
    - Moves the DMA manager to the Faulting state.
  - If ns = 1—The DMAC starts a DMA channel thread in the Non-secure state and programs the CNS bit to be non-secure.
- DMAWFE—The DMAC uses the status of the corresponding INS bit, in the CR3 register, to control whether it waits for the event.
  - If INS = 0—The event is in the Secure state. The DMAC:
    - Executes an NOP.
    - Sets the FSRD register.
    - Sets the mgr_evnt_err bit in the FTRD register.
    - Moves the DMA manager to the Faulting state.
  - If INS = 1—The event is in the Non-secure state. The DMAC halts execution of the thread and waits for the event to occur.
- DMASEV—The DMAC uses the status of the corresponding INS bit, in the CR3 register, to control if it creates the event interrupt.
  - If INS = 0—The event-interrupt resource is in the Secure state. The DMAC:
    - Executes a NOP.
    - Sets the FSRD register.
    - Sets the mgr_evnt_err bit in the FTRD register.
    - Moves the DMA manager to the Faulting state.
  - If INS = 1—The event-interrupt resource is in the Non-secure state. The DMAC creates the event interrupt.

DMA Channel Thread in Secure State

When the CNS bit is 0, the DMA channel thread is programmed to operate in the Secure state and it only performs secure instruction fetches.

When a DMA channel thread in the Secure state processes the following instructions:

- DMAWFE—The DMAC halts execution of the thread until the event occurs. When the event occurs, the DMAC continues execution of the thread, irrespective of the security state of the corresponding INS bit, in the CR3 register.
- DMASEV—The DMAC creates the event interrupt, irrespective of the security state of the corresponding INS bit, in the CR3 register.
- DMAWFP—The DMAC halts execution of the thread until the peripheral signals a DMA request. When this occurs, the DMAC continues execution of the thread, irrespective of the security state of the corresponding PNS bit, in the CR4 register.
- DMALDP and DMASTP—The DMAC sends a message to the peripheral to communicate that data transfer is complete, irrespective of the security state of the corresponding PNS bit, in the CR4 register.
- DMAFLUSHP—The DMAC clears the state of the peripheral and sends a message to the peripheral to resend its level status, irrespective of the security state of the corresponding PNS bit, in the CR4 register.

When a DMA channel thread is in the Secure state, it enables the DMAC to perform secure and non-secure AXI accesses.

DMA Channel Thread in Non-Secure State

When the CNS bit is 1, the DMA channel thread is programmed to operate in the Non-secure state and it only performs non-secure instruction fetches.

When a DMA channel thread in the Non-secure state processes the following instructions:

- DMAWFE—The DMAC uses the status of the corresponding INS bit, in the CR3 register, to control if it waits for the event.
    - If INS = 0—The event is in the Secure state. The DMAC:
        - Executes an NOP.
        - Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
        - Sets the ch_evnt_err bit in the FTRn register.
        - Moves the DMA channel to the Faulting completing state.
    - If INS = 1—The event is in the Non-secure state. The DMAC halts execution of the thread and waits for the event to occur.
- DMASEV—The DMAC uses the status of the corresponding INS bit, in the CR3 register, to control if it creates the event.
    - If INS = 0—The event-interrupt resource is in the Secure state. The DMAC:
        - Executes an NOP.
        - Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
        - Sets the ch_evnt_err bit in the FTRn register.
        - Moves the DMA channel to the Faulting completing state.
    - If INS = 1—The event-interrupt resource is in the Non-secure state. The DMAC creates the event interrupt.
- DMAWFP—The DMAC uses the status of the corresponding PNS bit, in the CR4 register, to control if it waits for the peripheral to signal a request.
    - If PNS = 0—The peripheral is in the Secure state. The DMAC:
        - Executes an NOP.
        - Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
        - Sets the ch_periph_err bit in the FTRn register.
        - Moves the DMA channel to the Faulting completing state.
    - If PNS = 1—The peripheral is in the Non-secure state. The DMAC halts execution of the thread and waits for the peripheral to signal a request.
- DMALDP and DMASTP—The DMAC uses the status of the corresponding PNS bit, in the CR4 register, to control if it sends an acknowledgement to the peripheral.
    - If PNS = 0—The peripheral is in the Secure state. The DMAC:
        - Executes an NOP.
        - Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
        - Sets the ch_periph_err bit in the FTRn register.
        - Moves the DMA channel to the Faulting completing state.
    - If PNS = 1—The peripheral is in the Non-secure state. The DMAC sends a message to the peripheral to communicate when the data transfer is complete.
- DMAFLUSHP—The DMAC uses the status of the corresponding PNS bit, in the CR4 register, to control if it sends a flush request to the peripheral.
    - If PNS = 0—The peripheral is in the Secure state. The DMAC:
        - Executes an NOP.
        - Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
        - Sets the ch_periph_err bit in the FTRn register.
        - Moves the DMA channel to the Faulting completing state.
    - If PNS = 1—The peripheral is in the Non-secure state. The DMAC clears the state of the peripheral and sends a message to the peripheral to resend its level status.

When a DMA channel thread is in the Non-secure state, and a DMAMOV CCR instruction attempts to program the channel to perform a secure AXI transaction, the DMAC:

1. Executes a DMANOP.
2. Sets the appropriate bit in the FSRC register that corresponds to the DMA channel number.
3. Sets the ch_rdwr_err bit in the FTR*n* register.
4. Moves the DMA channel thread to the Faulting completing state.

Programming Restrictions

Certain restrictions apply when programming the DMAC.

Fixed Unaligned Bursts

The DMAC does not support fixed unaligned bursts. If you program the following conditions, the DMAC treats this as a programming error:

- **Unaligned read**
  - src_inc field is 0 in the CCRn register.
  - The SARn register contains an address that is not aligned to the size of data that the src_burst_size field contains.
- **Unaligned write**
  - dst_inc field is 0 in the CCRn register.
  - The DARn register contains an address that is not aligned to the size of data that the dst_burst_size field contains.

Endian Swap Size Restrictions

If you program the endian_swap_size field in the CCRn register, to enable a DMA channel to perform an endian swap, then you must set the corresponding SAR register and the corresponding DARn register to contain an address that is aligned to the size that the endian_swap_size field specifies before executing any DMALD or DMAST instructions.

Note: If you update any of endian_swap_size, SARn , or DARn , for example, using a DMAADDH SAR instruction, then you must ensure that the SARn and DARn registers contain an address aligned to the size that the endian_swap_size field specifies before executing any additional DMALD or DMAST instructions.

If you program the src_inc field in the CCR register to use a fixed address, you must program the src_burst_size field to select a burst size that is greater than or equal to the value that the endian_swap_size field specifies. Similarly, if you program the dst_inc field to select a fixed destination address, you must program the dst_burst_size field to select a burst size that is greater than or equal to the value that the endian_swap_size field specifies.

If you program the dst_inc field in the CCRn register to use an incrementing address, you must program the CCRn register so that dst_burst_len times dst_burst_size is a multiple of endian_swap_size. For example, if endian_swap_size = 2, 32-bit, and dst_burst_size = 1, 2 bytes per beat, then you can program dst_burst_len = 1, 3, 5, ..., 15, that is 2, 4, 6, ..., 16 transfers.

Updating DMA Channel Control Registers During a DMA Cycle

Prior to the DMAC executing a sequence of DMALD and DMAST instructions, the values you program in to the CCRn register, SARn register, and DARn register control the data byte lane manipulation that the DMAC performs when it transfers the data from the source address to the destination address.

You can update these registers during a DMA cycle but if you change certain register fields then it can cause the DMAC to discard data. The following sections describe the register fields that might have a detrimental impact on a data transfer.

Updates that affect the destination address

If you use a DMAMOV instruction to update the DARn register or CCRn register part way through a DMA cycle then this might cause a discontinuity in the destination data stream.

A discontinuity occurs if you change any of the following:

- endian_swap_size field.
- dst_inc bit.
- dst_burst_size field when dst_inc = 0, that is, fixed-address burst.
- DARn register so that it modifies the destination byte lane alignment. Because the bus width is 64 bits, you change bits [2:0] in the DARn register.

When a discontinuity in the destination data stream occurs, the DMAC:

1. Halts execution of the DMA channel thread.
2. Completes all outstanding read and write operations for the channel. That is, as if the DMAC were executing DMARMB and DMAWMB.
3. Discards any residual MFIFO buffer data for the channel.
4. Resumes execution of the DMA channel thread.

Updates that affect the source address

If you use a DMAMOV instruction to update the SARn register or CCRn register part way through a DMA cycle then this might cause a discontinuity in the source data stream.

A discontinuity occurs if you change any of the following:

- src_inc bit.
- src_burst_size field.
- SAR register so that it modifies the source byte lane alignment. Because the bus width is 64 bits, you change bits [2:0] in the SAR register.

When a discontinuity in the source data stream occurs, the DMAC:

1. Halts execution of the DMA channel thread.
2. Completes all outstanding read operations for the channel. That is, as if the DMAC were executing DMARMB
3. Resumes execution of the DMA channel thread. No data is discarded from the MFIFO buffer.

Resource Sharing Between DMA Channels

DMA channel programs share the MFIFO buffer data storage resource. You must not start a set of concurrently running DMA channel programs with a resource requirement that exceeds 512, the size of the MFIFO buffer. If you exceed this limit then the DMAC might lock up and generate a Watchdog abort, refer to “Watchdog Abort”.

The DMAC includes a mechanism called the *load lock* to ensure that the shared MFIFO buffer resource is used correctly. The load-lock is either owned by one channel, or it is free. The channel that owns the load-lock can execute `DMALD` instructions successfully. A channel that does not own the load-lock pauses at a `DMALD` instruction until it takes ownership of the load-lock.

A channel claims ownership of the load lock when:

- It executes a `DMALD` or `DMALDP` instruction
- No other channel currently owns the load-lock.

A channel releases ownership of the load-lock when any of the following occur:

- It executes a `DMAST`, `DMASTP`, or `DMASTZ`
- It reaches a barrier, that is, it executes `DMARMB` or `DMAWMB`
- It waits, that is, it executes `DMAWFP` or `DMAWFE`
- It terminates normally, that is, it executes `DMAEND`
- It aborts for any reason, including `DMAKILL`.

The MFIFO buffer resource usage of a DMA channel program is measured in MFIFO buffer entries, and rises and falls as the program proceeds. The MFIFO buffer resource requirement of a DMA channel program is described using a *static requirement* and a *dynamic requirement* which are affected by the load-lock mechanism.

The static requirement is defined to be the maximum number of MFIFO buffer entries that a channel is currently using before that channel does one of the following:

- Executes a WFP or WFE instruction
- Claims ownership of the load-lock.

The dynamic requirement is defined to be the difference between the static requirement and the maximum number of MFIFO buffer entries that a channel program uses at any time during its

To calculate the total MFIFO buffer requirement, add the largest dynamic requirement to the sum of all the static requirements.

To avoid DMAC lockup, the total MFIFO buffer requirement of the set of channel programs must be equal to or less than 512, the MFIFO buffer depth.

Reset Manager on page 3-1

Constraints and Limitations of Use

DMA Channel Arbitration

The DMAC uses a round-robin scheme to serve the active DMA channels. To ensure that the DMAC continues to serve the DMA manager, it always serves the DMA manager prior to serving the next DMA channel.

You cannot alter the arbitration process of the DMAC.

DMA Channel Prioritization

The DMAC responds to all active DMA channels with equal priority. You cannot increase the priority of a DMA channel over any other DMA channels.

Instruction Cache Latency

When a cache miss occurs, most of the delay is introduced by the memory containing the DMA code; the DMAC adds minimal delay.

AXI Data Transfer Size

The DMAC can only perform data accesses up to 64 bits in width. If you program the `src_burst_size` or `dst_burst_size` fields to be larger, the DMAC indicates a precise abort.

Related Information

Abort Sources on page 16-16

AXI Bursts Crossing 4 KB Boundaries

The AXI specification does not permit AXI bursts to cross 4 KB address boundaries. If you program the DMAC with a combination of burst start address, size, and length that would cause a single burst to cross a 4 KB address boundary, then the DMAC generates a pair of bursts with a combined length equal to that specified. This operation is transparent to the DMAC channel thread program so that, for example, the DMAC responds to a single `DMALD` instruction by generating the appropriate pair of AXI read bursts.

AXI Burst Types

You can program the DMAC to generate only fixed-address or incrementing-address burst types for data accesses. It does not generate wrapping-address bursts for data accesses or for instruction fetches.

AXI Write Addresses

The DMAC can issue up to eight outstanding write addresses. The DMAC does not issue a write address until it has read in all of the data bytes required to fulfill that write transaction.

AXI Write Data Interleaving

The DMAC does not generate interleaved write data. All write data beats for one write transaction are output before any write data beat for the next write transaction.

DMA Controller Programming Model

Instruction Syntax Conventions

The following conventions are used in assembler syntax prototype lines and their subfields:

- < >

Any item bracketed by < and > is mandatory. A description of the item and of how it is encoded in the instruction is supplied by subsequent text.

- [ ]

Any item bracketed by [and] is optional. A description of the item and of how its presence or absence is encoded in the instruction is supplied by subsequent text.

- **Spaces**

To separate items, single spaces are used for clarity. When a space is obligatory in the assembler syntax, two or more consecutive spaces are used.

Instruction Set Summary

The DMAC instructions:

- Indicate a DMA prefix, to provide a unique name-space
- Have 8-bit opcodes that might use a variable data payload of 0, 8, 16, or 32 bits
- Indicate suffixes that are consistent.

Table 16-3: Instruction Syntax Summary

Mnemonic	Instruction	DMA Manager Usage	DMA Channel Usage	Description
DMAADDH	Add Halfword	No	Yes	DMAADDH on page 16-29
DMAADNH	Add Negative Halfword	No	Yes	DMAADNH on page 16-29
DMAEND	End	Yes	Yes	DMAEND on page 16-30

DMAWMB	Write Memory Barrier	No	Yes	DMAWMB on page 16-43

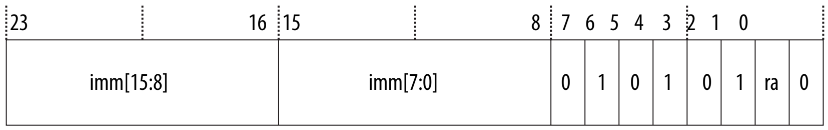
Instructions

DMAADDH

Add Halfword adds an immediate 16-bit value to the `SARn` register or `DARn` register, for the DMA channel thread. This enables the DMAC to support two-dimensional DMA operations.

Note: The immediate unsigned 16-bit value is zero-extended before the DMAC adds it to the address, using 32-bit addition. The DMAC discards the carry bit so that addresses wrap from 0xFFFFFFFF to 0x00000000.

Figure 16-5: DMAADDH Instruction Encoding



Assembler syntax

```
DMAADDH <address_register>, <16-bit bit immediate>
```

where:

`<address_register>` Selects the address register to use. It must be either:

- `SAR` `SAR`*n* register and sets `ra` to 0
- `DAR` `DAR`*n* register and sets `ra` to 1

`<16-bit immediate>` The immediate value to be added to the `<address_register>`.

Operation

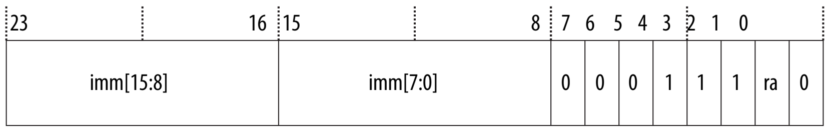
You can only use this instruction in a DMA channel thread.

DMAADNH

Add Negative Halfword adds an immediate negative 16-bit value to the `SARn` register or `DARn` register, for the DMA channel thread. This enables the DMAC to support two-dimensional DMA operations, or reading or writing an area of memory in a different order to naturally incrementing addresses.

Note: The immediate unsigned 16-bit value is one-extended to 32 bits, to create a value that is the two's complement representation of a negative number between -65536 and -1, before the DMAC adds it to the address using 32-bit addition. The DMAC discards the carry bit so that addresses wrap from 0xFFFFFFFF to 0x00000000. The net effect is to subtract between 65536 and 1 from the current value in the source or destination address register.

Figure 16-6: DMAADNH Encoding



Assembler syntax

```
DMAADNH <address_register>, <16 -bit immediate>
```

where:

`<address_register>` Selects the address register to use. It must be either:

`SAR` `SAR`*n* register and sets `ra` to 0

`DAR` `DAR`*n* register and sets `ra` to 1

`<16- bit immediate>` The immediate value to be added to the `<address_register>`.

Note: You should specify the 16-bit immediate as the number that is to be represented in the instruction encoding. For example, `DMAADNH DAR`, 0xFFF0 causes the value 0xFFFFFFF0 to be added to the current value of the Destination Address register, effectively subtracting 16 from the `DAR`.

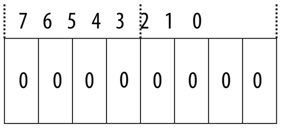
Operation

You can only use this instruction in a DMA channel thread.

DMAEND

End signals to the DMAC that the DMA sequence is complete. After all DMA transfers are complete for the DMA channel, the DMAC moves the channel to the Stopped state. It also flushes data from the MFIFO buffer and invalidates all cache entries for the thread.

Figure 16-7: DMAEND Instruction Encoding



Assembler syntax

```
DMAEND
```

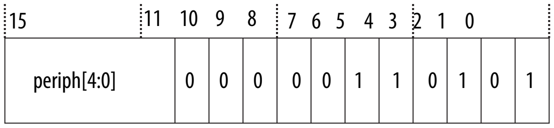
Operation

You can use the instruction with the DMA manager thread and the DMA channel thread.

DMAFLUSHP

Flush Peripheral clears the state in the DMAC that describes the contents of the peripheral and sends a message to the peripheral to resend its level status.

Figure 16-8: DMAFLUSHP Instruction Encoding



Assembler syntax

```
DMAFLUSHP <peripheral>
```

where:

`<peripheral>` 5-bit immediate, value 0-31

Operation

You can only use this instruction in a DMA channel thread.

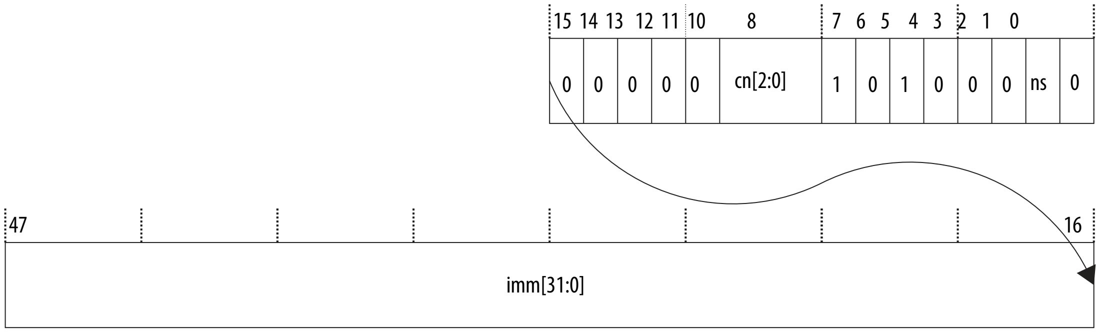
DMAGO

When the DMA manager executes Go for a DMA channel that is in the Stopped state, it performs the following steps on the DMA channel:

1. Moves a 32-bit immediate into the program counter
2. Sets its security state
3. Updates it to the Executing state.

Note: If a DMA channel is not in the Stopped state when the DMA manager executes `DMAGO` then the DMAC does not execute `DMAGO` but instead it executes `DMANOP`.

Figure 16-9: DMAGO Instruction Encoding



Assembler syntax

`DMAGO <channel_number>, <32- bit_immediate>` [, `ns`]

where:

`<channel_number>` Selects a DMA channel. It must be one of:

`C0` DMA channel 0

`C1` DMA channel 1

`C2` DMA channel 2

`C3` DMA channel 3

`C4` DMA channel 4

`C5` DMA channel 5

`C6` DMA channel 6

`C7` DMA channel 7

Note: If you provide a channel number that is not available for your configuration of the DMAC, the DMA manager thread aborts.

`<32- bit_immediate>` The immediate value that is written to the `CPC` *n* register for the selected `<channel_number>`.

`[ns]`

- If `ns` is present, the DMA channel operates in the Non-secure state.
- Otherwise, the execution of the instruction depends on the security state of the DMA manager:

DMA manager is in the Secure state—DMA channel operates in the Secure state.

DMA manager is in the Non-secure state—The DMAC aborts.

Operation

You can only use this instruction with the DMA manager thread.

DMAKILL

Kill instructs the DMAC to immediately terminate execution of a thread. Depending on the thread type, the DMAC performs the following steps:

DMA Manager Thread

1. Invalidates all cache entries for the DMA manager.
2. Moves the DMA manager to the Stopped state.

DMA Channel Thread

1. Moves the DMA channel to the Killing state.
2. Waits for AXI transactions, with an ID equal to the DMA channel number, to complete.
3. Invalidates all cache entries for the DMA channel.
4. Remove all entries in the MFIFO buffer for the DMA channel.
5. Remove all entries in the read buffer queue and write buffer queue for the DMA channel.
6. Moves the DMA channel to the Stopped state.

Figure 16-10: DMAKILL Instruction Encoding

7	6	5	4	3	2	1	0
0	0	0	0	0	0	0	1

Assembler syntax

`DMAKILL`

Operation

You can use the instruction with the DMA manager thread and the DMA channel thread.

Note: You must not use the `DMAKILL` instruction in DMA channel programs. To issue a `DMAKILL` instruction, use the `DBGINST0` register.

DMALD[S | B]

Load instructs the DMAC to perform a DMA load, using AXI transactions that the source address registers and channel control registers specify. It places the read data into the MFIFO buffer and tags it with the corresponding channel number. `DMALD` is an unconditional instruction but `DMALDS` and `DMALDB` are conditional on the state of the `request_type` flag. If the `src_inc` bit in the channel control registers is set to incrementing, the DMAC updates the source address registers after it executes `DMALD[S|B]`.

Note: The DMAC sets the value of `request_type` when it executes a `DMAWFP` instruction.

Figure 16-11: DMALD[S|B] Instruction Encoding

7	6	5	4	3	2	1	0
0	0	0	0	0	1	bs	x

Assembler syntax

`DMALD[S|B]`

where:

`[S]` If S is present, the assembler sets `bs` to 0 and `x` to 1. The instruction is conditional on the state of the `request_type` flag:

- `request_type` = Single

The DMAC performs a `DMALD` instruction and it sets `arlen[3:0]`=0x0 so that the AXI read transaction length is one. The DMAC ignores the value of the src_burst_len field in the channel control registers.

- `request_type` = Burst

The DMAC performs a `DMANOP` instruction. The DMAC increments the channel PC to the next instruction. No state change occurs.

`[B]` If B is present, the assembler sets `bs` to 1 and `x` to 1. The instruction is conditional on the state of the `request_type` flag:

- `request_type` = Single

The DMAC performs a `DMANOP` instruction. The DMAC increments the channel PC to the next instruction. No state change occurs.

- `request_type` = Burst

The DMAC performs a `DMALD`.

If you do not specify the S or B operand, the assembler sets `bs` to 0 and `x` to 0, and the DMAC always executes a DMA load.

Operation

You can only use this instruction in a DMA channel thread. If you specify the S or B operand, execution of the instruction is conditional on the state of `request_type` matching that of the instruction.

DMALDP<S | B>

Load and notify Peripheral instructs the DMAC to perform a DMA load, using AXI transactions that source address registers and channel control registers specify. It places the read data into a FIFO buffer that is tagged with the corresponding channel number and after it receives the last data item, it sends an acknowledgement to the peripheral that the data transfer is complete. If the `src_inc` bit in the channel control registers is set to incrementing, the DMAC updates source address registers after it executes `DMALDP<S|B>`.

Figure 16-12: DMALDP<S|B> Instruction Encoding

15 11	10	9	8	7	6	5	4	3	2	1	0
periph[4:0]	0	0	0	0	0	1	0	0	1	bs	1

Assembler syntax

`DMALDP<S|B> <peripheral>`

where:

`<S>` When S is present, the assembler sets `bs` to 0. The instruction is conditional on the state of the `request_type` flag:

- `request_type` = Single

The DMAC performs a `DMALDP` instruction and it sets `arlen[3:0]`=0x0 so that the AXI read transaction length is one. The DMAC ignores the value of the src_burst_len field in the channel control registers.

- `request_type` = Burst

The DMAC performs a `DMANOP`.

`<B>` When B is present, the assembler sets `bs` to 1. The instruction is conditional on the state of the `request_type` flag:

- `request_type` = Single

The DMAC performs a `DMANOP`.

- `request_type` = Burst

The DMAC performs a load using a burst DMA transfer.

`<peripheral>` 5-bit immediate, value 0-31.

Note: The DMAC sets the value of the `request_type` flag when it executes a `DMAWFP` instruction.

Operation

You can only use this instruction in a DMA channel thread. Execution of the instruction is conditional on the state of the `request_type` flag matching that of the instruction.

DMALP

Loop instructs the DMAC to load an 8-bit value into the loop counter register you specify.

This instruction indicates the start of a section of instructions, and you set the end of the section using the `DMALPEND` instruction. The DMAC repeats the set of instructions that you insert between `DMALP` and `DMALPEND` until the value in the loop counter register reaches zero.

Note: The DMAC saves the value of the PC for the instruction that follows `DMALP`. After the DMAC executes `DMALPEND`, and the loop counter register is not zero, this enables it to execute the first instruction in the loop.

Figure 16-13: DMALP Instruction Encoding

15 … 8	7	6	5	4	3	2	1	0
iter[7:0]	0	0	1	0	0	0	1c	0

Assembler syntax

`DMALP <loop_iterations>`

where:

`<loop_iterations>`

Specifies the number of loops to perform, range 1-256.

- The assembler determines the loop counter register to use and either:
- Sets `lc` to 0, and the DMAC writes the value loop_iterations minus 1 to the loop counter 0 registers
- Sets `lc` to 1, and the DMAC writes the value loop_iterations minus 1 to the loop counter 1 registers.

Operation

You can only use this instruction in a DMA channel thread.

DMALPEND[S | B]

Loop End indicates the last instruction in the program loop but the behavior of the DMAC depends on whether `DMALP` or `DMALPFE` starts the loop. If a loop starts with:

- `DMALP` The loop has a defined loop count and `DMALPEND[S|B]` instructs the DMAC to read the value of the loop counter register. If a loop counter register returns:
  - Zero—The DMAC executes a `DMANOP` and therefore exits the loop.
  - Nonzero—The DMAC decrements the value in the loop counter register and updates the thread PC to contain the address of the first instruction in the program loop, that is, the instruction that follows the `DMALP`.
- `DMALPFE` The loop has an undefined loop count and the DMAC uses the state of the `request_last` flag to control when it exits the loop. If the `request_last` flag is:
  - 0—The DMAC updates the thread PC to contain the address of the first instruction in the program loop, that is, the instruction that follows the `DMALP`.
  - 1—The DMAC executes a `DMANOP` and therefore exits the loop.

Figure 16-14: DMALPEND[S|B] Instruction Encoding

15 … 8	7	6	5	4	3	2	1	0
backwards_jump[7:0]	0	0	1	nf	1	lc	bs	x

Assembler syntax

`DMALPEND[S|B]`

where:

[S] If S is present and the loop starts with DMALP, then the assembler sets bs to 0 and x to 1. The instruction is conditional on the state of the request_type flag:

- request_type = Single
  - The DMAC executes the DMALPEND
- request_type = Burst
  - The DMAC performs a DMANOP and therefore exits the loop.

[B] If B is present and the loop starts with DMALP, then the assembler sets bs to 1 and x to 1. The instruction is conditional on the state of the request_type flag:

- request_type = Single
  - The DMAC performs a DMANOP and therefore exits the loop.
- request_type = Burst
  - The DMAC executes the DMALPEND

If you do not specify the S or B operand, the assembler sets bs to 0 and x to 0, and the DMAC always executes the DMALPEND.

Note: You must not specify the S or B operand when a loop starts with DMALPFE. If you do, the assembler issues a warning message and sets bs to 0, x to 0, and nf to 1. In the same way as for DMALPFE, the DMAC uses the state of the request_last flag to control when it exits the loop.

Note: The DMAC sets the value of the:

- request_type flag when it executes a DMAWFP instruction.
- request_last flag to 1 when the corresponding peripheral issues the last request command through the peripheral request interface.

To correctly assign the additional bits in the DMALPEND instruction, the assembler determines the values for:

backwards_jump[7:0] Sets the relative location of the first instruction in the program loop. The assembler calculates the value for backwards_jump[7:0] by subtracting the address of the first instruction in the loop from the address of the DMALPEND.

- nf sets it to:
  - 0 if DMALPFE started the program loop
  - 1 if DMALP started the program loop.
- lc sets it to:
  - 0 if the loop counter 0 registers contains the loop counter value
  - 1 if the loop counter 1 registers contains the loop counter value
  - 1 if DMALPFE started the program loop.

Operation

You can only use this instruction in a DMA channel thread. If you specify the S or B operand, execution of the instruction is conditional on the state of the request_type flag matching that of the instruction.

Related Information

- Peripheral Length Management on page 16-11

- **DMAWFP** on page 16-42

DMALPFE

The assembler uses Loop Forever to configure certain bits in DMALPEND.

Note: When the assembler encounters DMALPFE, it does not create an instruction for the DMAC, but instead, it modifies the behavior of DMALPEND. The insertion of DMALPFE in program code identifies the start of the loop.

Assembler syntax

```
DMALPFE
```

Related Information

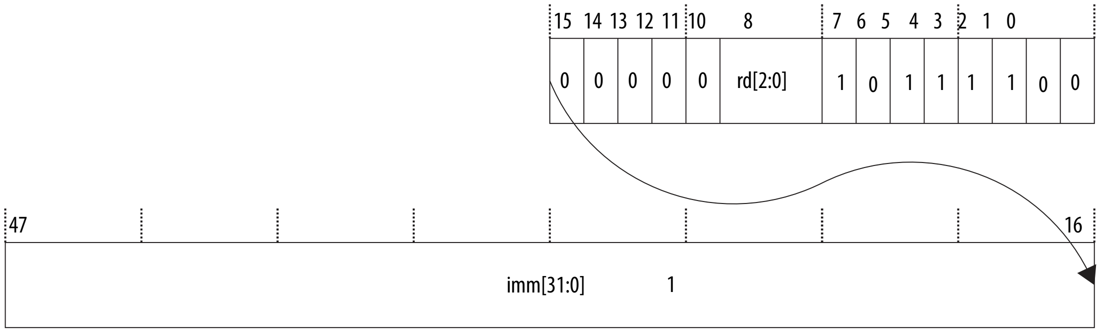
DMALPEND[S | B] on page 16-35

DMAMOV

Move instructs the DMAC to move a 32-bit immediate into the following registers:

- source address registers
- destination address registers
- channel control registers

Figure 16-15: DMAMOV Instruction Encoding



Assembler syntax

```
DMAMOV <destination_register>, <32- bit_immediate>
```

where:

```
<destination_register>
```

The valid registers are:

- SAR—selects the source address registers and sets rd to b000
- CCR—selects the channel control registers and sets rd to b001
- DAR—selects the destination address registers and sets rd to b010

```
<32 -bit_immediate>
```

A 32-bit value that is written to the specified destination register.

Note: For information about using the assembler to program the various fields that the channel control registers, refer to DMAMOV CCR section

Operation

You can only use this instruction in a DMA channel thread.

Related Information

DMAMOV CCR on page 16-44
Information about using the assembler to program the various fields that the channel control registers

DMANOP

No Operation does nothing. You can use this instruction for code alignment purposes.

Figure 16-16: DMANOP Instruction Encoding

7	6	5	4	3	2	1	0
0	0	0	1	1	0	0	0

Assembler syntax

```
DMANOP
```

Operation

You can use the instruction with the DMA manager thread and the DMA channel thread.

DMARMB

Read Memory Barrier forces the DMA channel to wait until all of the executed `DMALD` instructions for that channel have been issued on the AXI master interface and have completed.

This enables write-after-read sequences to the same address location with no hazards.

Figure 16-17: DMARMB Instruction Encoding

7	6	5	4	3	2	1	0
0	0	0	1	0	0	1	0

Assembler syntax

```
DMARMB
```

Operation

You can only use this instruction in a DMA channel thread.

DMASEV

Send Event instructs the DMAC to modify an event-interrupt resource. Depending on how you program the interrupt enable register, this either:

- Generates event <event_num>

  Note: Typically, you use `DMAWFE` to stall a thread and then another thread executes `DMASEV`, using the appropriate event number, to unstall the waiting thread.
- Signals an interrupt using `irq <event_num>`.

Figure 16-18: DMASEV Instruction Encoding

15 … 11	10	9	8	7	6	5	4	3	2	1	0
event_num[4:0]	0	0	0	0	0	1	1	0	1	0	0

Assembler syntax

```
DMASEV <event_num>
```

where:

`<event_num>` 5-bit immediate, value 0-31

Note: The DMAC aborts the thread if you select an event number that is not available.

Operation

You can use the instruction with the DMA manager thread and the DMA channel thread.

Related Information

- **Using Events and Interrupts** on page 16-14
- **Using an Event to Restart DMA Channels** on page 16-14

DMAST[S | B]

Store instructs the DMAC to transfer data from the FIFO buffer to the location that the destination address registers specifies, using AXI transactions that the DA register and channel control registers specify. If the `dst_inc` bit in the channel control registers is set to incrementing, the DMAC updates the destination address registers after it executes `DMAST[S|B]`.

Figure 16-19: DMAST[S|B] Instruction Encoding

7	6	5	4	3	2	1	0
0	0	0	0	1	0	bs	x

Assembler syntax

```
DMAST[S|B]
```

where:

[S] If S is present, the assembler sets bs to 0 and x to 1. The instruction is conditional on the state of the request_type flag:

- request_type = Single
- The DMAC performs a DMAST instruction and it sets awlen[3:0]=0x0 so that the AXI write transaction length is one. The DMAC ignores the v value of the dst_burst_len field in the channel control registers.
- request_type = Burst
- The DMAC performs a DMANOP instruction. The DMAC increments the channel PC to the next instruction. No state change occurs.

[B] If B is present, the assembler sets bs to 1 and x to 1. The instruction is conditional on the state of the request_type flag:

- request_type = Single
- The DMAC performs a DMANOP instruction. The DMAC increments the channel PC to the next instruction. No state change occurs.
- request_type = Burst
- The DMAC performs a DMAST.
- If you do not specify the S or B operand, the assembler sets bs to 0 and x to 0, and the DMAC always executes a DMA store.

Note: The DMAC sets the value of the request_type flag when it executes a DMAWFP instruction.

Operation

You can only use this instruction in a DMA channel thread. If you specify the S or B operand, execution of the instruction is conditional on the state of the request_type flag matching that of the instruction.

The DMAC only commences the burst when the MFIFO buffer contains all of the data necessary to complete the burst transfer.

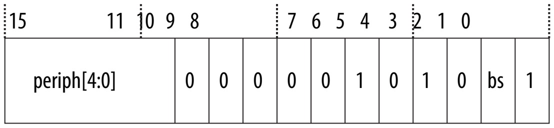
Related Information

DMAWFP on page 16-42

DMASTP<S | B>

Store and notify Peripheral instructs the DMAC to transfer data from the FIFO buffer to the location that the destination address registers specifies, using AXI transactions that the DA register and channel control registers specify. It uses the DMA channel number to access the appropriate location in the FIFO buffer. After the DMA store is complete, and the DMAC has received a buffered write response, it issues an acknowledgement to the peripheral that the data transfer is complete. If the dst_inc bit in the channel control registers is set to incrementing, the DMAC updates the destination address registers after it executes DMASTP<S|B>.

Figure 16-20: DMASTP<S|B> Instruction Encoding



Assembler syntax

```
DMASTP<S|B> <peripheral>
```

where:

`<S>` Sets `bs` to 0. This instructs the DMAC to perform:

- A single DMA store operation if `request_type` is programmed to Single
- The DMAC ignores the state of the dst_burst_len field in the channel control registers and always performs an AXI transfer with a burst length of one.
- A `DMANOP` if `request_type` is programmed to Burst.

`<B>` Sets `bs` to 1. This instructs the DMAC to perform:

- The DMA store if `request_type` is programmed to Burst
- A `DMANOP` if `request_type` is programmed to Single.

`<peripheral>` 5-bit immediate, value 0-31.

Note: The DMAC sets the value of the `request_type` flag when it executes a `DMAWFP` instruction.

Operation

You can only use this instruction in a DMA channel thread.

The DMAC only commences the burst when the MFIFO buffer contains all of the data necessary to complete the burst transfer.

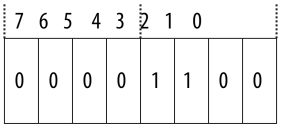
Related Information

DMAWFP on page 16-42

DMASTZ

Store Zero instructs the DMAC to store zeros, using AXI transactions that the destination address registers and channel control registers specify. If the `dst_inc` bit in the channel control registers is set to incrementing, the DMAC updates the destination address registers after it executes `DMASTZ`.

Figure 16-21: DMASTZ Instruction Encoding



Assembler syntax

```
DMASTZ
```

Operation

You can only use this instruction in a DMA channel thread.

DMAWFE

Wait For Event instructs the DMAC to halt execution of the thread until the event, that <event_num> specifies, occurs. When the event occurs, the thread moves to the Executing state and the DMAC clears the event.

Figure 16-22: DMAWFE Instruction Encoding

15	11	10	9	8	7	6	5	4	3	2	1	0
event_num[4:0]		0	i	0	0	0	1	1	0	1	1	0

Assembler syntax

`DMAWFE <event_num>[, invalid]`

where:

`<event_num>` 5-bit immediate, value 0-31

`[invalid]` Sets `i` to 1. If `invalid` is present, the DMAC invalidates the instruction cache for the current DMA thread. If `invalid` is not present, then the assembler sets `i` to 0 and the DMAC does not invalidate the instruction cache for the current DMA.

- The DMAC aborts the thread if you select an event number that is not available for your configuration of the DMAC. To ensure cache coherency, you must use `invalid` when a processor writes the instruction stream for a DMA channel.

Operation

You can use the instruction with the DMA manager thread and the DMA channel thread.

Related Information

Using Events and Interrupts on page 16-14

DMAWFP

Wait For Peripheral instructs the DMAC to halt execution of the thread until the specified peripheral signals a DMA request for that DMA channel.

Figure 16-23: DMAWFP Instruction Encoding

15	11	10	9	8	7	6	5	4	3	2	1	0
peripheral[4:0]		0	0	0	0	0	1	1	0	0	bs	p

Assembler syntax

`DMAWFP <peripheral>, <single|burst|periph>`

where:

`<peripheral>` 5-bit immediate, value 0-31

Note: The DMAC aborts the thread if you select a peripheral number that is not available.

`<single>` Sets `bs` to 0 and `p` to 0. This instructs the DMAC to continue executing the DMA channel thread after it receives a single or burst DMA request. The DMAC sets the `request_type` to Single, for that DMA channel.

`<burst>` Sets `bs` to 1 and `p` to 0. This instructs the DMAC to continue executing the DMA channel thread after it receives a burst DMA request. The DMAC sets the `request_type` to Burst.

Note: The DMAC ignores single burst DMA requests.

`<periph>` Sets `bs` to 0 and `p` to 1. This instructs the DMAC to continue executing the DMA channel thread after it receives a single or burst DMA request. The DMAC sets the `request_type` to:

- **Single:** When it receives a single DMA request.
- **Burst:** When it receives a burst DMA request.

Operation

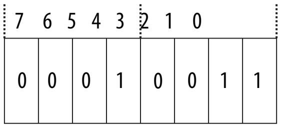
You can only use this instruction in a DMA channel thread.

DMAWMB

Write Memory Barrier forces the DMA channel to wait until all of the executed `DMAST` instructions for that channel have been issued on the AXI master interface and have completed.

This permits read-after-write sequences to the same address location with no hazards.

Figure 16-24: DMAWMB Instruction Encoding



7	6	5	4	3	2	1	0
0	0	0	1	0	0	1	1

Assembler syntax

`DMAWMB`

Operation

You can only use this instruction in a DMA channel thread.

Assembler Directives

The assembler provides several additional commands.

DCD

Assembler directive to place a 32-bit immediate in the instruction stream.

Syntax

DCD imm32

DCB

Assembler directive to place an 8-bit immediate in the instruction stream.

Syntax

DCB imm8

DMALP

Assembler directive to insert an iterative loop.

Syntax

DMALP [<LC0>|<LC1>] `<loop_iterations>`

where:

`<loop_iterations>`

An 8-bit value that specifies the number of loops to perform.

Note: For clarity in writing assembler instructions, the 8-bit value is the actual number of iterations of the loop to be executed. The assembler decrements this by one to create the actual value, 0-255, that the DMAC uses.

`[LC0]` If `LC0` is present, the DMAC stores `<loop_iterations>` in the loop counter 0 registers.

`[LC1]` If `LC1` is present, the DMAC stores `<loop_iterations>` in the loop counter 1 registers.

Note: If `LC0` or `LC1` is not present, the assembler determines the loop counter register to use.

DMALPFE

Assembler directive to insert a repetitive loop.

Syntax

DMALPFE

Enables the assembler to clear the `nf` bit that is present in `DMALPEND[S | B]`.

DMAMOV CCR

Assembler directive that enables you to program the channel control registers using the specified format.

Syntax

DMAMOV CCR,

```
[SB<1-16>] [SS<8|16|32|64|128>] [SA<I|F>]

[SP<imm3>] [SC<imm4>]

[DB<1-16>] [DS<8|16|32|64|128>] [DA<I|F>]

[DP<imm3>] [DC<imm4>]

[ES<8|16|32|64|128>]
```

Table 16-4: DMAMOV CCR argument description and the default values

Syntax	Description	Options	Default

SA	Source address increment. Sets the value of `arburst[0]`	I = Increment
		F = Fixed
			I

SS	Source burst size in bits. Sets the value of `arsize[2:0]`	8, 16, 32, or 64	8

Syntax	Description	Options	Default
SB	Source burst length. Sets the value of `arlen[3:0]`	1 to 16	1
SP	Source protection	0 to 7[1]	0
SC	Source cache	0 to 15[1,2]	0

DA	Destination address increment. Sets the value of `awburst[0]`	I = Increment
		F = Fixed
			I

DS	Destination burst size in bits. Sets the value of `awsize[2:0]`	8, 16, 32, or 64	8
DB	Destination burst length. Sets the value of `awlen[3:0]`	1 to 16	1
DP	Destination protection	0 to 7[1]	0
DC	Destination cache	0 to 15[1,3]	0
ES	Endian swap size, in bits	8, 16, 32, or 64	8

Note: **1.** You must use decimal values when programming this immediate value.
2. Because the DMAC ties ARCACHE[3] LOW, the assembler always sets bit 3 to 0 and uses bits [2:0] of your chosen value for SC.
3. Because the DMAC ties AWCACHE[2] LOW, the assembler always sets bit 2 to 0 and uses bit [3] and bits [1:0] of your chosen value for DC.

MFIFO Buffer Usage Overview

About MFIFO Buffer Usage Overview

The MFIFO buffer is a shared resource that is utilized on a first-come, first-served basis by all currently active channels. To a program, it appears as a set of variable-depth parallel FIFO buffers, one per channel, with the restriction that the total depth of all the Fifes cannot exceed the buffer depth, 512. The width of the AXI master interface is the same as the MFIFO buffer width.

The DMAC is capable of realigning data from the source to the destination. For example, the DMAC shifts the data by two byte lanes when it reads a word from address 0x103 and writes to address 0x205. All byte manipulations occur when data enters the MFIFO buffer, as a result of an AXI read due to a `DMALD` instruction, so that the DMAC does not need to manipulate the data when it removes it from the MFIFO buffer, as a result of an AXI write due to a `DMAST` instruction. Therefore the storage and packing of the data in the MFIFO buffer is determined by the destination address and transfer characteristics.

When a program specifies that incrementing transactions are to be performed to the destination, the DMAC packs data into the MFIFO buffer to minimize the usage of the MFIFO buffer entries. For example, the DMAC packs two 32-bit words into a single entry in the MFIFO buffer when the DMAC has a 64-bit AXI data bus and the program uses a source address of 0x100, and destination address of 0x200.

In certain situations, the number of entries required to store the data loaded from a source is not a simple calculation of amount of source data divided by MFIFO buffer width. The calculation of the number of entries required is not simple when any of the following occur:

- The source address is not aligned to the AXI bus width.
- The destination address is not aligned to the AXI bus width.
- The transactions are to a fixed destination, that is, a non-incrementing address.

The DMALD and DMAST instructions each specify that an AXI transaction is to be performed. The amount of data transferred by an AXI transaction depends on the values programmed in to the CCR *n* register and the address of the transaction.

The following sections provide several example DMAC programs together with illustrations of the MFIFO buffer usage.

Note: These sections show MFIFO buffer usage in the following ways:

- A graph of the number of MFIFO buffer entries versus time
- A diagram of the byte-lane manipulation that the DMAC performs when data enters the MFIFO buffer.

Note: The numbers 0 and 7 in the MFIFO buffer diagrams indicate the byte lanes in the MFIFO buffer.

Information about unaligned transfers available from the ARM info center website.

Aligned Transfers

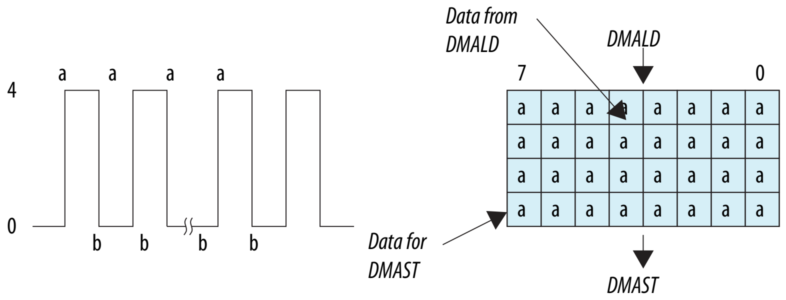
Simple Aligned Program

The following program shows the MFIFO buffer usage. In this program, the source address and destination address are aligned with the AXI data bus width.

```
DMAMOV CCR, SB4 SS64 DB4 DS64
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4000
DMALP 16
    DMALD shown as a in figure below
DMALPEND
DMAEND
```

Figure 16-25: Simple Aligned Program

Each DMALD requires four entries and each DMAST removes four entries.



This example has a static requirement of zero MFIFO buffer entries and a dynamic requirement of four MFIFO buffer entries.

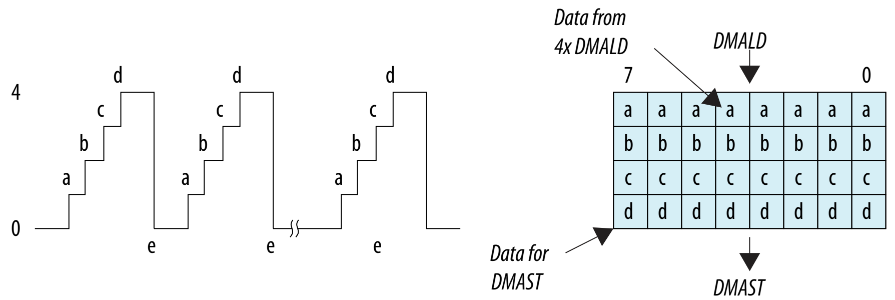
Aligned Asymmetric Program with Multiple Loads

The following program performs four loads for each store and the source address and destination address are aligned with the AXI data bus width.

```
DMAMOV CCR, SB1 SS64 DB4 DS64
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4000
DMALP 16
    DMALD ; shown as a in the figure below
    DMALD ; shown as b in the figure below
    DMALD ; shown as c in the figure below
    DMALD ; shown as d in the figure below
    DMAST ; shown as e in the figure below
DMALPEND
DMAEND
```

Figure 16-26: Aligned Asymmetric Program with Multiple Loads

Each `DMALD` requires one entry and each `DMAST` removes four entries.



This example has a static requirement of zero MFIFO buffer entries and a dynamic requirement of four MFIFO buffer entries.

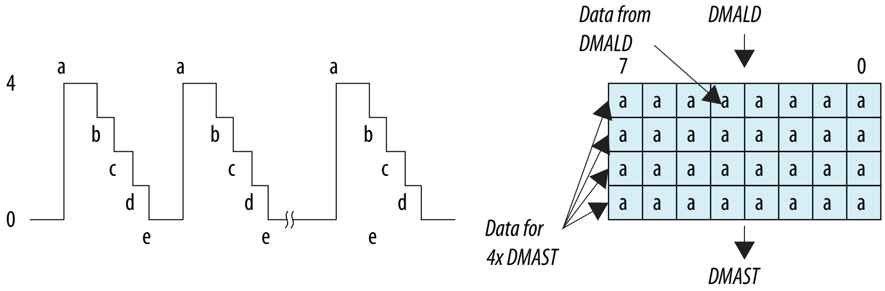
Aligned Asymmetric Program with Multiple Stores

The following program performs four stores for each load and the source address and destination address are aligned with the AXI data bus width.

```
DMAMOV CCR, SB4 SS64 DB1 DS64
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4000
DMALP 16
    DMALD ; shown as a in the figure below
    DMAST ; shown as b in the figure below
    DMAST ; shown as c in the figure below
    DMAST ; shown as d in the figure below
    DMAST ; shown as e in the figure below
DMALPEND
DMAEND
```

Figure 16-27: Aligned Asymmetric Program with Multiple Stores

Each DMALD requires four entries and each DMAST removes one entry.



This example has a static requirement of zero MFIFO buffer entries and a dynamic requirement of four MFIFO buffer entries.

Unaligned Transfers

Aligned Source Address to Unaligned Destination Address

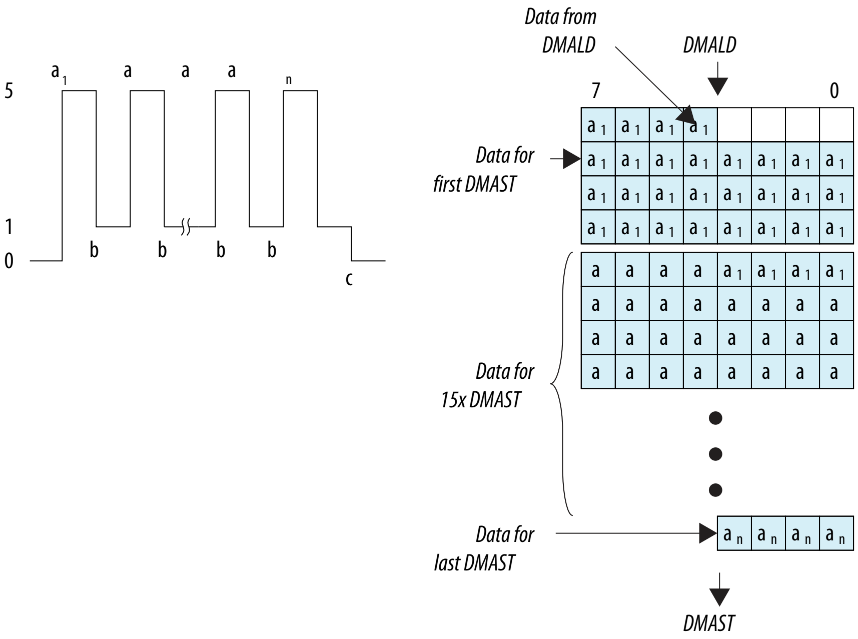
In the following program, the source address is aligned with the AXI data bus width but the destination address is unaligned. The destination address is not aligned to the destination burst size so the first DMAST instruction removes less data than the first DMALD instruction reads. Therefore, a final DMAST of a single word is required to clear the data from the MFIFO buffer.

```
DMAMOV CCR, SB4 SS64 DB4 DS64
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4004
DMALP 16
    DMALD ; shown as a1, ... a, an in the figure below
    DMAST ; shown as b in the figure below
DMALPEND
DMAMOV CCR, SB4 SS64 DB1 DS32
DMAST ; shown as c in the figure below
DMAEND
```

Figure 16-28: Aligned to Unaligned Program

The first DMALD instruction loads four doublewords but because the destination address is unaligned, the DMAC shifts them by four bytes and therefore it uses five entries in the MFIFO buffer.

Each DMAST requires only four entries of data, and therefore the extra entry remains in use for the duration of the program, until it is emptied by the last DMAST.



This example has a static requirement of one MFIFO buffer entry and a dynamic requirement of four MFIFO buffer entries.

Unaligned Source Address to Aligned Destination Address

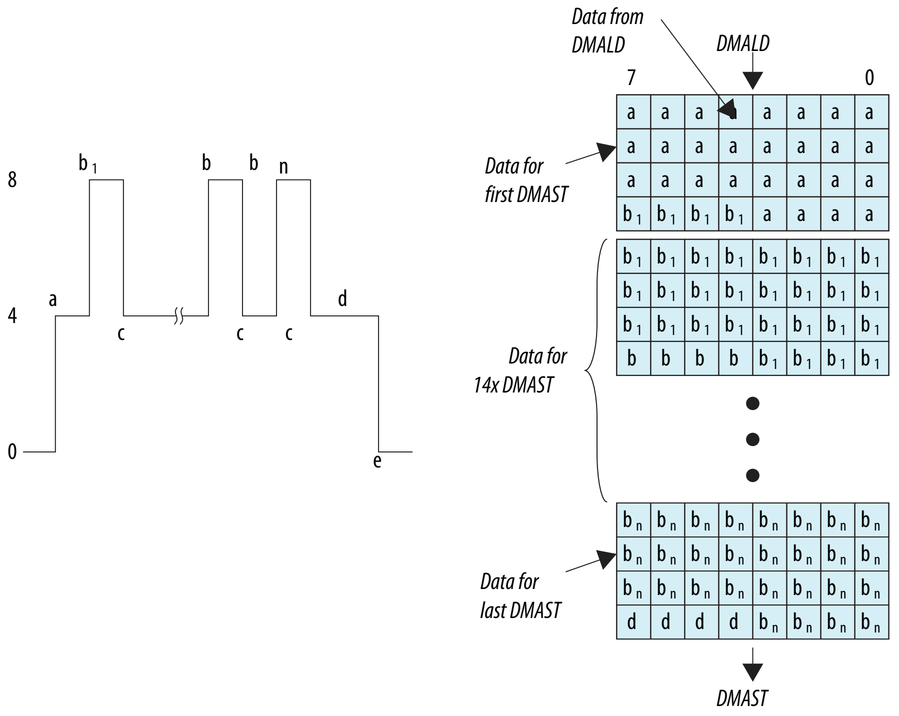
In this program, the source address is unaligned with the AXI data bus width but the destination address is aligned. The source address is not aligned to the source burst size so the first DMALD instruction reads in less data than the DMAST. Therefore, an extra DMALD is required to satisfy the first DMAST.

```
DMAMOV CCR, SB4 SS64 DB4 DS64
DMAMOV SAR, 0x1004
DMAMOV DAR, 0x4000
DMALD ; shown as a in the figure below
DMALP 15
    DMALD ; shown as b1, ... b, bn in the figure below
    DMAST ; shown as c in the figure below
DMALPEND
DMAMOV CCR, SB1 SS32 DB4 DS64
DMALD ; shown as d in the figure below
DMAST ; shown as e in the figure below
DMAEND
```

Figure 16-29: Unaligned to Aligned Program

The first DMALD instruction does not load sufficient data to enable the DMAC to execute a DMAST and therefore the program includes an additional DMALD, prior to the start of the loop.

After the first DMALD, the subsequent DMALDs align with the source burst size. This optimizes the p performance but it requires a larger number of MFIFO buffer entries.



Note: The DMALD shown as **d** does not increase the MFIFO buffer usage because it loads four bytes into an MFIFO buffer entry that the DMAC has already allocated to this channel.

This example has a static requirement of four MFIFO buffer entries and a dynamic requirement of four MFIFO buffer entries.

Unaligned Source Address to Aligned Destination Address with Excess Initial Load

This program is an alternative to that described in *Unaligned Source Address to Aligned Destination Address*. The program executes a different sequence of source bursts which might be less efficient, but require fewer MFIFO buffer entries.

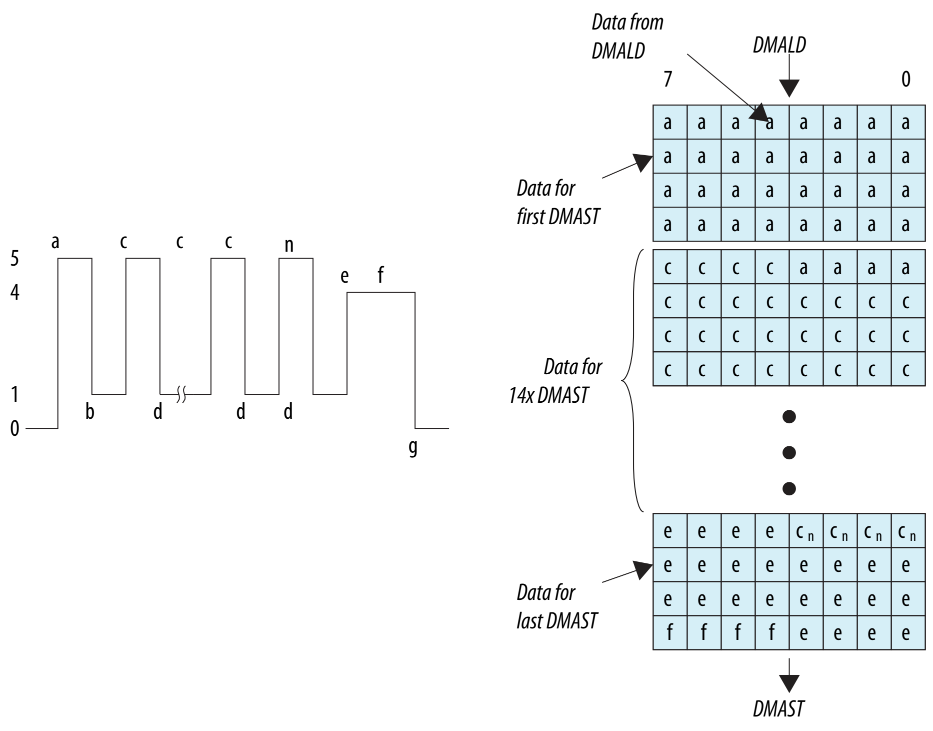
```
DMAMOV CCR, SB5 SS64 DB4 DS64
DMAMOV SAR, 0x1004
DMAMOV DAR, 0x4000
DMALD ; shown as a in the figure below
DMAST ; shown as b in the figure below
DMAMOV CCR, SB4 SS64 DB4 DS64
DMALP 14
    DMALD ; shown as c and cn in the figure below
DMALPEND
DMAMOV CCR, SB3 SS64 DB4 DS64
DMALD ; shown as e in the figure below
DMAMOV CCR, SB1 SS32 DB4 DS64
DMALD ; shown as f in the figure below
```

```
DMAST ; shown as g in the figure below
DMAEND
```

Figure 16-30: Unaligned to Aligned with Excess Initial Load

The first DMALD instruction loads five bursts of data to enable the DMAC to execute the first DMAST.

After the first DMALD, the subsequent DMALDs are not aligned to the source burst size, for example the second DMALD reads from address 0x1028. After the loop, the final two DMALDs read the data required to satisfy the final DMAST.



Note: The DMALD shown as **f** does not increase the MFIFO buffer usage because it loads four bytes into an MFIFO buffer entry that the DMAC has already allocated to this channel.

This example has a static requirement of one MFIFO buffer entry and a dynamic requirement of four MFIFO buffer entries.

Related Information

Unaligned Source Address to Aligned Destination Address on page 16-49

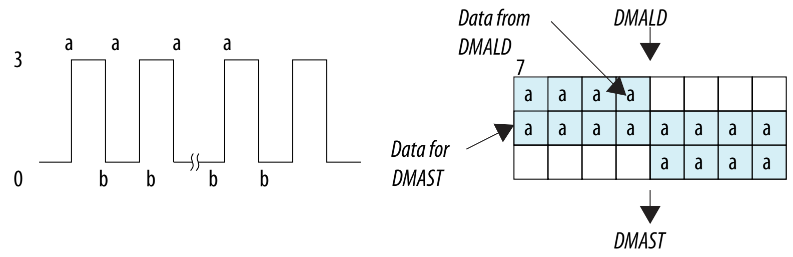
Aligned Burst Size Unaligned MFIFO Buffer

In this program, the destination address, which is narrower than the MFIFO buffer width, aligns with the burst size, but does not align with the MFIFO buffer width.

```
DMAMOV CCR, SB4 SS32 DB4 DS32
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4004
DMALP 16
 DMALD ; shown as a in the figure below
 DMAST ; shown as b in the figure below
```

```
DMALPEND
DMAEND
```

Figure 16-31: Aligned Burst with Unaligned MFIFO Buffer Width



In this example, the destination address is not 64-bit aligned, it requires three rather than the expected two MFIFO buffer entries.

This example has a static requirement of zero MFIFO buffer entries and a dynamic requirement of three MFIFO buffer entries.

Fixed Transfers

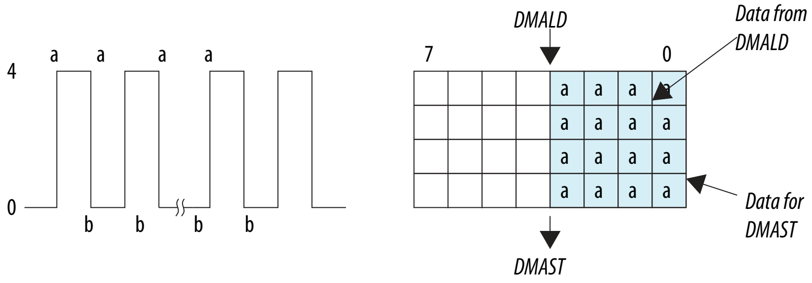
Fixed Destination with Aligned Address

In this program, the source address and destination address are aligned with the AXI data bus width, and the destination address is fixed.

```
DMAMOV CCR, SB2 SS64 DB4 DS32 DAF
DMAMOV SAR, 0x1000
DMAMOV DAR, 0x4000
DMALP 16
    DMALD ; shown as a in the figure below
    DMAST ; shown as b in the figure below
DMALPEND
DMAEND
```

Figure 16-32: Fixed Destination with Aligned Address

Each DMALD in the program loads two 64-bit data transfers into the MFIFO buffer. Because the destination address is a 32-bit fixed address, then the DMAC splits each 64-bit data item across two entries in the MFIFO buffer.

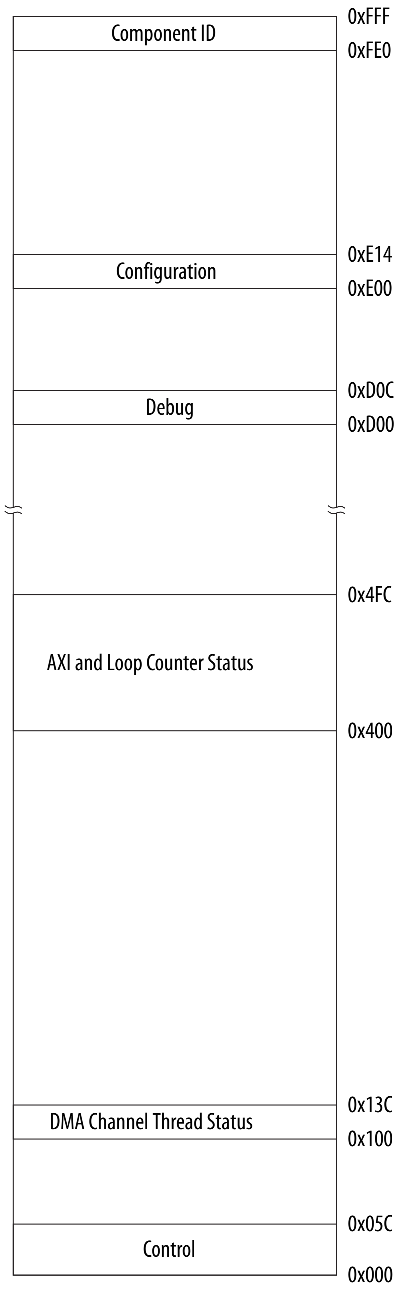


This example has a static requirement of zero MFIFO buffer entries and a dynamic requirement of four MFIFO buffer entries.

DMA Controller Registers

The following DMAC register map spans a 4 KB region, consists of the following sections.

Figure 16-33: DMAC Summary Register Map



- **Control registers**— allow you to control the DMAC.
- **DMA channel thread status registers**—provide the status of the DMA channel threads.
- **AXI and loop counter status registers**—provide the AXI transfer status and the loop counter status, for each DMA channel thread.
- **Debug registers**—enable the following functionality:
    - Allow you to send instructions to a thread when debugging the program code.
    - Allow system firmware to send instructions to the DMA manager thread.
- **Configuration registers**—enable system firmware to identify the configuration of the DMAC and control the behavior of the watchdog.
- **Component ID registers**— enable system firmware to identify peripherals. Do not attempt to access reserved or unused address locations. Attempting to access these locations can result in an unpredictable behavior.

Ethernet Media Access Controller 17

2014.06.30

cv_54017 Subscribe Send Feedback

The hard processor system (HPS) provides two Ethernet media access controller (EMAC) peripherals. Each EMAC can be used to transmit and receive data at 10/100/1000 Mbps over Ethernet connections in compliance with the IEEE 802.3 specification. The EMACs are instances of the Synopsys DesignWare 3504-0 Universal 10/100/1000 Ethernet MAC (DWC_gmac).

The EMAC has an extensive memory-mapped control and status register (CSR) set, which can be accessed by the ARM Cortex-A9® MPCore.

For an understanding of this chapter, you should be familiar with the basics of IEEE 802.3 media access control (MAC).

[40]

Features of the Ethernet MAC

MAC

- IEEE 802.3-2008 compliant
- Data rates of 10/100/1000 Mbps
- IEEE 802.3x flow control in full-duplex
- Full duplex and half duplex modes
- IEEE 802.3x flow control automatic transmission of zero-quanta pause frame on flow control input deassertion

Synopsys expressly disclaims any and all warranties, express, implied, or otherwise, including the implied warranties of merchantability, fitness for a particular purpose, and non-infringement, and any warranties arising out of a course of dealing or usage of trade.

†Paragraphs marked with the dagger (†) symbol are Synopsys Proprietary. Used with permission.

- Optional forwarding of received pause control frames to the user
- Packet bursting and frame extension in 1000 Mbps half-duplex
- IEEE 802.3x flow control in full-duplex
- Back-pressure support for half-duplex
- IEEE 1588-2002 and IEEE 1588-2008 precision networked clock synchronization
- IEEE 802.3-az, version D2.0 for Energy Efficient Ethernet (EEE)
- IEEE 802.1Q virtual local area network (VLAN) tag detection for reception frames
- Preamble and start-of-frame data (SFD) insertion in transmit and deletion in receive paths
- Automatic cyclic redundancy check (CRC) and pad generation controllable on a per-frame basis
- Options for automatic pad/CRC stripping on receive frames
- Programmable frame length supporting standard and jumbo Ethernet frames (with size up to 16 KB)
- Programmable inter-frame gap (IFG), from 40- to 96-bit times in steps of eight

PHY Interface

- Reduced Gigabit Media Independent Interface (RGMII) for 10/100/1000
- Gigabit Media Independent Interface (GMII) through the FPGA fabric
- Serial Gigabit Media Independent Interface (SGMII) supported through the GMII to FPGA fabric
- Media Independent Interface (MII) through the FPGA fabric
- Management Data Input/Output (MDIO) (IEEE 802.3) or I^{2}C PHY management interface

DMA Interface

- 32-bit interface
- Programmable burst size for optimal bus utilization
- Single-channel mode transmit and receive engines
- Byte-aligned addressing mode for data buffer support
- Dual-buffer (ring) or linked-list (chained) descriptor chaining
- Descriptors can each transfer up to 8 KB of data

Management Interface

- 32-bit host interface to CSR set
- Comprehensive status reporting for normal operation and transfers with errors
- Configurable interrupt options for different operational conditions
- Per-frame transmit/receive complete interrupt control
- Separate status returned for transmission and reception packets

Acceleration

- Transmit and receive checksum offload for transmission control protocol (TCP), user datagram protocol (UDP), or Internet control message protocol (ICMP) over Internet protocol (IP)

Other Features

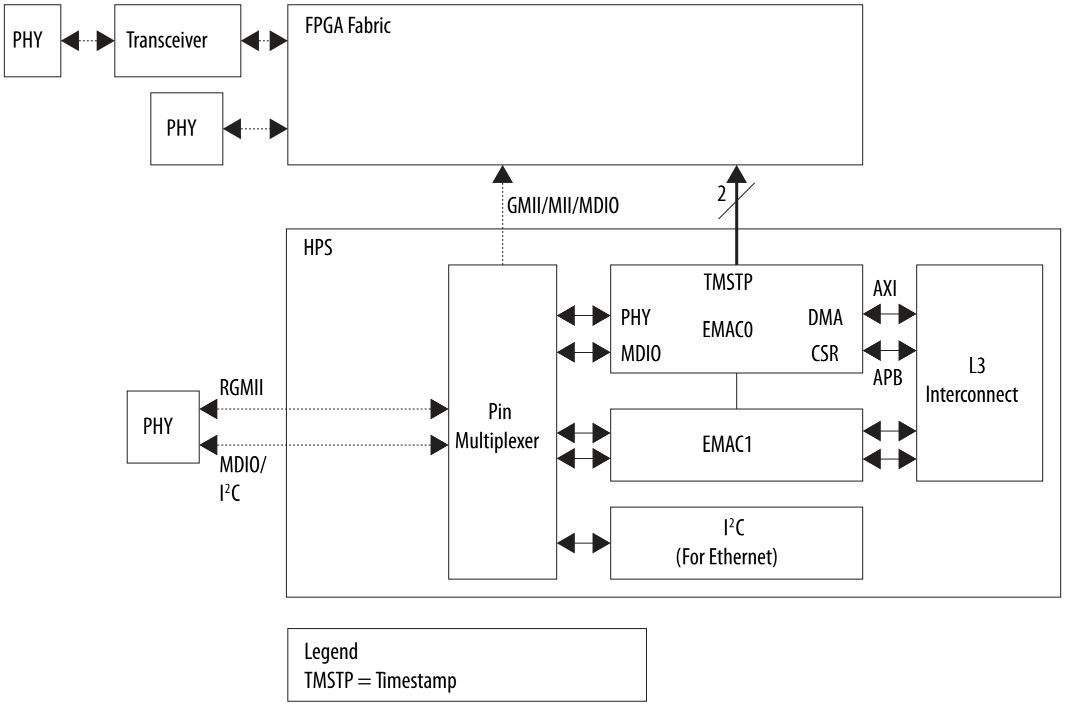
- Supports a variety of flexible address filtering modes
- Up to 31 additional 48-bit perfect destination address (DA) filters with masks for each byte
- Up to 31 48-bit source address (SA) comparison check with masks for each byte
- 256-bit hash filter (optional) for multicast and uni-cast DAs

- Option to pass all multicast addressed frames
- Promiscuous mode support to pass all frames without any filtering for network monitoring
- Passes all incoming packets (as per filter) with a status report

EMAC Block Diagram and System Integration

Figure 17-1: EMAC System Integration

EMAC integration from a high level point of view.



The EMACs are integrated into the HPS portion of the system on a chip (SoC) device. They communicate with the I/O pins.

EMAC to RGMII Interface

Table 17-1: External PHY Datapath In/Out Interface

EMAC Port		In/Out	Width	Description
clk_tx_i	Transmit Clock	In	1	This signal provides the transmit clock for RGMII (125/25/2.5 MHz in 1G/100M/10Mbps). All PHY transmit signals generated by the EMAC are synchronous to this clock.

EMAC Port		In/Out	Width	Description
phy_txd_o	PHY Transmit Data	Out	8	This is a group of eight transmit data signals driven by the MAC. Unused bits in the RGMII interface configuration are tied to low. RGMII: Bits [3:0] provide the RGMII transmit data. The data bus changes with both rising and falling edges of the transmit clock (clk_tx_i). The validity of the data is qualified with phy_txen_o. Synchronous to: clk_tx_i, clk_tx_180_i
phy_txen_o	PHY Transmit Data Enable	Out	1	This signal is driven by the EMAC component. RGMII: This signal is the control signal (rgmii_tctl) for the transmit data, and is driven on both edges of the clock. Synchronous to: clk_tx_i, clk_tx_180_i
rst_clk_tx_n_o	Transmit clock reset output.	Out	1	Transmit clock reset output.
clk_rx_i	Receive Clock	In	1	Clock frequency is 125/25/2.5 MHz in 1 G/100 M/10 Mbps modes. It is provided by the external PHY. All PHY signals received by the EMAC are synchronous to this clock.
phy_rxd_i	PHY Receive Data	In	8	This is a bundle of eight data signals received from the PHY. RGMII: Bits [3:0] provide the RGMII receive data. The data bus is sampled with both rising and falling edges of the receive clock (clk_rx_i). The validity of the data is qualified with phy_rxdv_i. Synchronous to: clk_rx_i, clk_rx_180_i
phy_rxdv_i	PHY Receive Data Valid	In	1	This signal is driven by PHY. RGMII: This is the receive control signal used to qualify the data received on phy_rxd. This signal is sampled on both edges of the clock. Synchronous to: clk_rx_i, clk_rx_180_i
rst_clk_rx_n_o	Receive clock reset output.	Out	1	Receive clock reset output.

EMAC Port		In/Out	Width	Description
phy_intf_sel_i[1:0]	PHY Interface Select	In	2	These pins select one of the PHY interfaces of the EMAC. This signal is sampled only during reset assertion and ignored after that. • 01: RGMII • 00, 10, and 11: Invalid
clk_ref_i	EMAC Reference Clock	In	1	This is the reference clock to the EMAC. The clock is emac0_clk or emac1_clk supplied by the clock manager. The system manager drives the phy_intf_sel signal to control which clock is used. The clock rate is 250 MHz.

EMAC to FPGA PHY Interface

Table 17-2: EMAC to FPGA PHY Interface Signals

Signal Name		In/Out	Width	Description
phy_tx_i	Transmit Clock	In	1	This is the transmit clock (2.5 MHz/25 MHz) provided by the MII PHYs only. This clock comes from the FPGA Interface and is used for TX data capture.
phy_txclk_o	Transmit Clock Output	Out	1	Transmit clock output to the PHY to sample data. For MII this clock is unused. For GMII (1G - 125 MHz) and RGMII (125/25/2.5 MHz), this clock is derived from the clk_ref_i 250 MHz input.

Signal Name		In/Out	Width	Description
phy_txd_o	PHY Transmit Data	Out	8	These are a group of eight transmit data signals driven by the MAC. Unused bits in the RGMII interface configuration are driven low. The following functions depend on which PHY interface is selected: • GMII: All eight bits provide the GMII transmit data byte. For the lower speed MII operation, only the low 4 bits are used. The validity of the data is qualified with phy_txen_o and phy_txer_o. Synchronous to: phy_ clk_tx_o. • RGMII: Bits [3:0] provide the RGMII transmit data. The data bus changes with both rising and falling edges of the transmit clock (clk_tx_o). The validity of the data is qualified with phy_txen_o. Synchronous to: phy_clk_tx_o (both the rising and falling edges).
phy_txen_o	PHY Transmit Data Enable	Out	1	This signal is driven by the EMAC component and has the following function listed below: • GMII: When high, indicates that valid data is being transmitted on the phy_txd bus. Synchronous to: clk_tx_o

Signal Name		In/Out	Width	Description
phy_txer_o	PHY Transmit Error	Out	1	This signal is driven by the MAC and has multiple functions depending on which PHY interface is selected, as explained below: • GMII / MII: When high, indicates a transmit error or carrier extension on the phy_txd bus. Also used for signaling of low power states in Energy Efficient Ethernet operation. Synchronous to: phy_clk_tx_o. • RGMII: Not used. Tied low in some configurations; driven low in others.
rst_clk_tx_n_o	Transmit Clock Reset output	Out	1	Transmit clock reset output to the FPGA fabric: This is the internal synchronized reset to clk_tx_int output from the EMAC. May be used by logic implemented in the FPGA fabric as desired.
phy_clk_rx_i	Receive Clock	In	1	Receive clock from external PHY. For RGMII, the clock frequency is 125/25/2.5 MHz in 1 G, 100 M, and 10 Mbps modes. For GMII, the clock frequency is 125 MHz.

Signal Name		In/Out	Width	Description
phy_rxd_i	PHY Receive Data	In	8	This is a bundle of eight data signals received from the PHY. It has multiple functions depending on which PHY interface is selected, as listed below: • GMII: All 8 bits provide the GMII receive data byte. The validity of the data is qualified with phy_rxdv_i and phy_rxer_i. For lower speed MII operation, only the bottom 4 bits are used. Synchronous to: phy_ clk_rx_i. • RGMII: Bits [3:0] provide the RGMII receive data. The data bus is sampled on both rising and falling edges of the receive clock (phy_clk_rx_i). The validity of the data is qualified with phy_rxdv_i. Synchronous to: phy_ clk_rx_i (both rising and falling edges).
phy_rxdv_i	PHY Receive Data Valid	In	1	This signal is driven by PHY and has multiple functions depending on which PHY interface is selected, as listed below: • GMII: When high, indicates that the data on the phy_rxd bus is valid. It remains asserted continuously from the first recovered byte of the frame through the final recovered byte. Synchronous to: phy_ clk_rx_i • RGMII: This is the receive control signal (RX_CTL) used to qualify the data received on phy_rxd. On the rising edge of the clock, rxdv is sampled. On the falling edge of the clock, rxdv XOR rxerr is sampled. Synchronous to: phy_clk_rx_i, both rising and falling edges.

Signal Name		In/Out	Width	Description
phy_rxer_i	PHY Receive Error	In	1	This signal is driven by the PHY. In GMII / MII mode, it indicates an error or carrier extension (GMII) in the received frame. Synchronous to: phy_clk_rx_i, This signal is not used in RGMII mode.
rst_clk_rx_n_o	Receive clock reset output.	Out	1	Receive clock reset output.
phy_crs_i	PHY Carrier Sense	In	1	This signal, valid only in the GMII / MII mode, is asserted by the PHY when either the transmit or receive medium is not idle. The PHY de-asserts this signal when both transmit and receive medium are idle. This signal is not synchronous to any clock.
phy_col_i	PHY Collision Detect	In	1	PHY Collision Detect. This signal, valid only in GMII / MII mode operating in half duplex, is asserted by the PHY when a collision is detected on the medium. This signal is not synchronous to any clock.
gmii_mdi_i	MDIO signal input	In	1	This signal is driven synchronously with the gmii_mdc_o clock.
gmii_mdo_o	MDIO signal data out	Out	1	MDIO signal data out. This signal is driven synchronously with the gmii_mdc_o clock.
gmii_mdo_o_e	MDIO signal output enable	Out	1	MDIO signal output enable. This signal is driven synchronously with the gmii_mdc_o clock.
gmii_mdc_o	Management Data Clock	Out	1	The maximum frequency of this clock is 2.5 MHz. This clock is generated from the application clock through a clock divider.

PHY Management Interface

The HPS can provide support for either MDIO or I^{2}C PHY management interfaces.

MDIO Interface

The MDIO interface signals are synchronous to l4_mp_clk in all supported modes.

Table 17-3: PHY MDIO Management Interface

Signal	In/Out	Width	Description
gmii_mdi_i	In	1	Management Data In. The PHY generates this signal to transfer register data during a read operation. This signal is driven synchronously with the gmii_mdc_o clock.
gmii_mdo_o	Out	1	Management Data Out. The EMAC uses this signal to transfer control and data information to the PHY.
gmii_mdo_o_e	Out	1	Management Data Output Enable. This enable signal drives the gmii_mdo_o signal from an external three-state I/O buffer. This signal is asserted whenever valid data is driven on the gmii_mdo_o signal. The active state of this signal is high.
gmii_mdc_o	Out	1	Management Data Clock. The EMAC provides timing reference for the gmii_mdi_i and gmii_mdo_o signals on MII through this aperiodic clock. The maximum frequency of this clock is 2.5 MHz. This clock is generated from the application clock through a clock divider.

I^{2}C External PHY Management Interface

Some PHY devices use the I^{2}C instead of MDIO for their control interface. Small form factor pluggable (SFP) optical or pluggable modules are often among those with this interface.

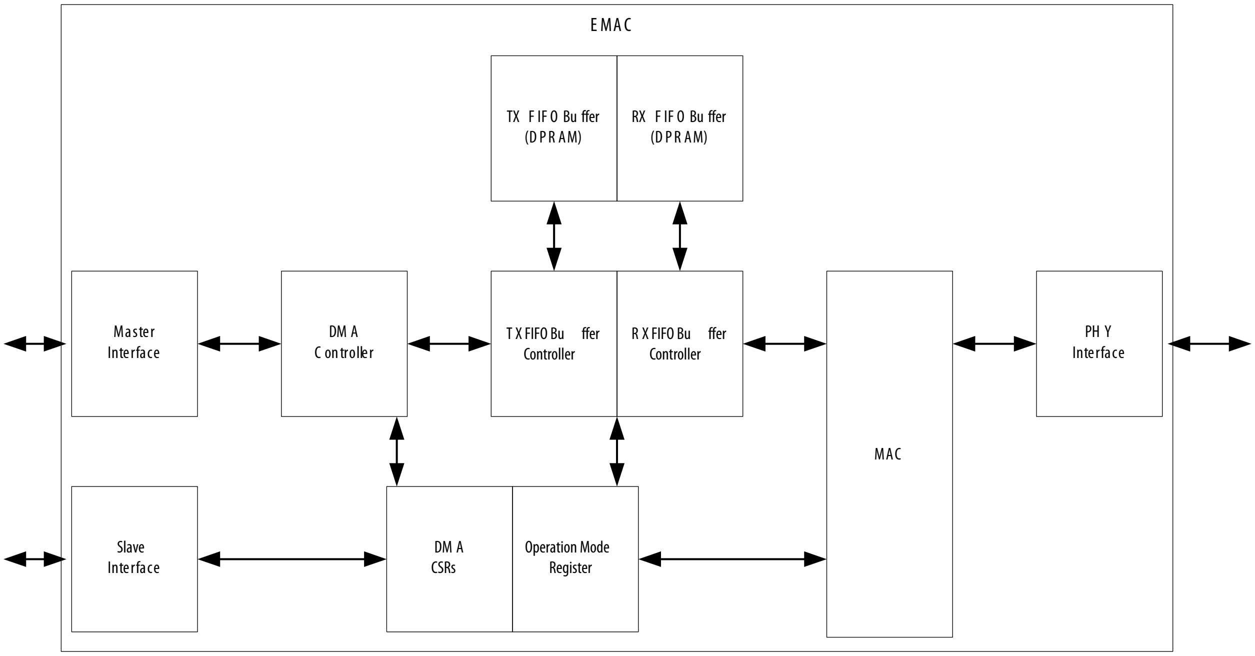
The HPS can use two of the four general purpose I^{2}C peripherals for controlling the PHY devices.

IEEE 1588

The EMAC supports IEEE 1588 operation in all modes with a resolution of one µs. It can be used by the ARM® Cortex™-A9 microprocessor unit (MPU) subsystem to maintain synchronization between the time counters internal to the two MACs.

Functional Description of the EMAC

Figure 17-2: EMAC High-Level Block Diagram with Interfaces



There are two host interfaces to the MAC. The management host interface, a 32-bit slave interface, provides access to the CSR set. The data interface is a 32-bit interface. It controls data transfer between the direct memory access (DMA) controller channels and the rest of the HPS system through the NIC 301 L3 interconnect.

There is a built-in DMA controller which is optimized for data transfer between the MAC controller and system memory. The DMA controller has independent transmit and receive engines, and a CSR set. The transmit engine transfers data from system memory to the device port, while the receive engine transfers data from the device port to the system memory. The controller uses descriptors to efficiently move data from source to destination with minimal host intervention.

The EMAC also contains FIFO buffer memory to buffer and regulate the Ethernet frames between the application system memory and the EMAC controller. On transmit, the Ethernet frames read into the transmit FIFO buffer (1024 x 42 bits), and eventually trigger the MAC to perform the transfer. Received Ethernet frames are stored in the receive FIFO buffer, also indicating the FIFO buffer bits fill level to the DMA controller. The DMA controller then initiates the configured burst transfers. Both receive and transmit transfer status are taken from the MAC and transferred to the DMA.

Host Interfaces

There are two host interfaces in the EMAC: a slave and a master. The master is connected to the L3 master peripheral switch interface in the L3 interconnect block.

Slave

The EMAC CSR set access is provided by a slave interface. The slave is connected to the level 4 (L4) bus.

DMA Master

The DMA interface is provided by a master interface. Two types of data are transferred on the interface: data descriptors and actual data packets. The interface is very efficient in transferring full duplex Ethernet packet traffic. Read and write data transfers from different DMA channels can be performed simultaneously on this port. The only exceptions to this are transmit descriptor reads and write-backs which cannot happen simultaneously.

DMA transfers are split into a software configurable number of burst transactions on the interface. The AXI_Bus_Mode register in the dmagrp group is used to configure bursting behavior.

The interface assigns a unique ID for each DMA channel and also for each read DMA or write DMA request in a channel. Data transfers with distinct IDs can be reordered and interleaved.

Write data transfers are generally performed as posted writes with OK responses returned as soon as the interconnect has accepted the last beat of a data burst. Descriptors (status or timestamp) however are always transferred as non-posted writes in order to prevent race conditions with the transfer complete interrupt logic.

The slave may issue an error response. When that happens, the EMAC disables the DMA channel which generated the original request and asserts an interrupt signal. The host needs to reset the EMAC with a hard or soft reset to restart the DMA to recover from this condition.

The EMAC supports up to 16 outstanding transactions on the interface. Buffering outstanding transactions smooths out back pressure behavior. This is important when resource contention bottlenecks arise under high system load conditions.

Cache Control Interface

The system manager provides the values for the master cache outputs through this interface. These inputs are used as the outputs to the L3 interconnect extending the capabilities of this block with respect to the cacheable characteristics of master transfers.

To configure EMAC DMA controller to perform cacheable accesses, configure the cache bits in the system manager. Register bits should be accessed only when the master interface is guaranteed to be in an inactive state.

Related Information

System Manager on page 5-1

External PHY

The following PHY interfaces are supported for the HPS:

- RGMII for 10/100/1000

The EMAC also has a control interface used for configuration and status monitoring of the PHY. In this case, the PHY is the slave device. There are two choices of control interface:

- MDIO
- I^{2}C interface

The MDIO interface is built into the EMAC while the I^{2}C interface uses separate I^{2}C peripherals residing on the HPS. The interfaces are multiplexed externally to the EMAC.

Transmit and Receive Data FIFO Buffers

Each EMAC component has associated transmit and receive data FIFO buffer instances. Both FIFO buffer instances are 1024 x 42 bits. The FIFO buffer word consists of:

- Data: 32 bits
- Sideband:
    - Byte enables (BE): 2 bits
    - End of frame (EOF): 1 bit
    - Error correction code (ECC): 7 bits

The data and sideband are protected by the 7-bit single error correct, double error detect (SEC-DED) code word. These FIFO buffer RAMs also contain ECC enable, error injection and status pins. The enable and error injection pins are inputs driven by the system manager and the status pins are outputs driven to the MPU subsystem.

Note: The ECC block provides outputs to notify the system manager when single-bit correctable errors are detected (and corrected) and when double-bit uncorrectable errors are detected. The ECC logic also allows the injection of single-bit and double-bit errors for test purposes.

IEEE 1588-2002 Timestamps

The IEEE 1588-2002 standard defines the Precision Time Protocol (PTP) which enables precise synchronization of clocks in a distributed network of devices. The PTP applies to systems communicating by local area networks supporting multicast messaging. This protocol enables heterogeneous systems that include clocks of varying inherent precision, resolution, and stability to synchronize. It is frequently used in automation systems where a collection of communicating machines such as robots must be synchronized and hence operate over a common time base.[(†)]

The PTP is transported over UDP/IP. The system or network is classified into Master and Slave nodes for distributing the timing and clock information.†

The following figure shows the process that PTP uses for synchronizing a slave node to a master node by exchanging PTP messages.

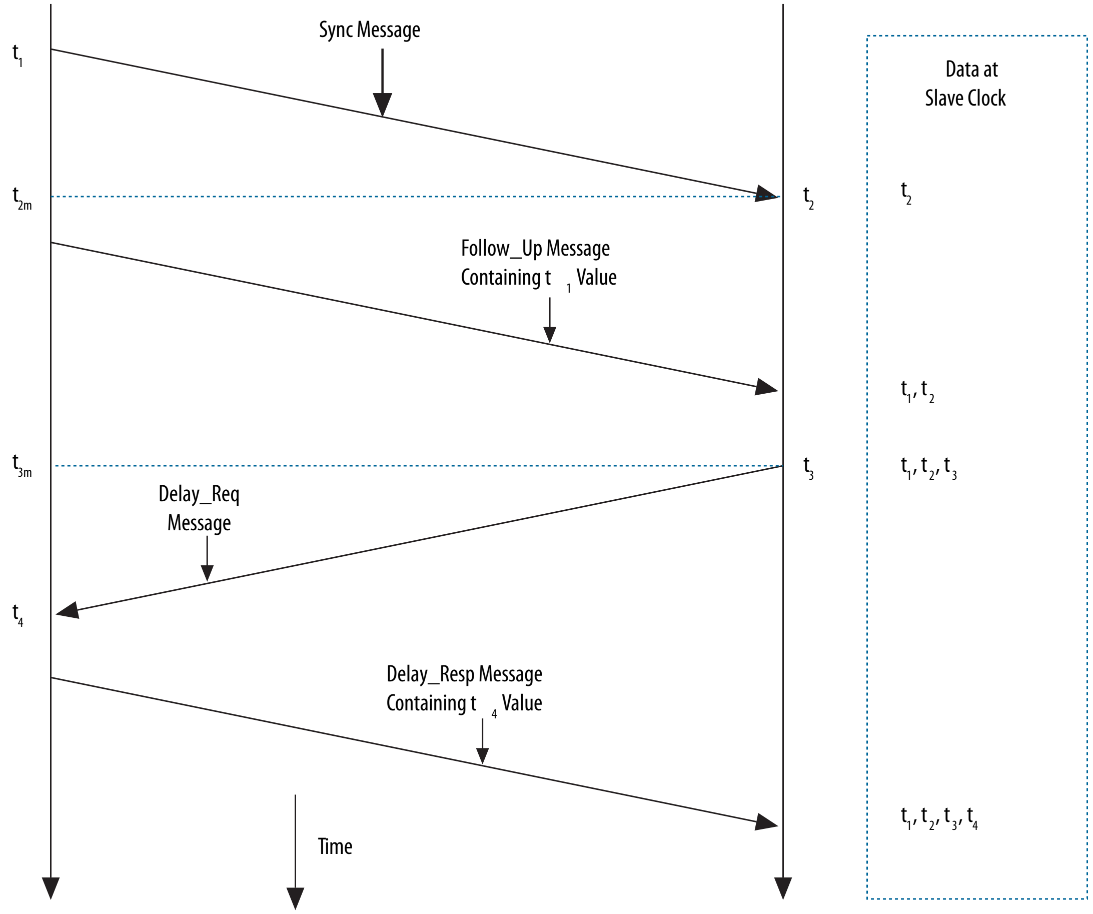
†Paragraphs marked with the dagger (†) symbol are Synopsys Proprietary. Used with permission.

Figure 17-3: Networked Time Synchronization



The PTP uses the following process for synchronizing a slave node to a master node by exchanging the PTP messages:

1. The master broadcasts the PTP Sync messages to all its nodes. The Sync message contains the master's reference time information. The time at which this message leaves the master's system is t1. This time must be captured, for Ethernet ports, at the PHY interface.†
2. The slave receives the sync message and also captures the exact time, t2, using its timing reference.†
3. The master sends a follow_up message to the slave, which contains t1 information for later use.†
4. The slave sends a delay_req message to the master, noting the exact time, t3, at which this frame leaves the PHY interface.†
5. The master receives the message, capturing the exact time, t4, at which it enters its system.†
6. The master sends the t4 information to the slave in the delay_resp message.†
7. The slave uses the four values of t1, t2, t3, and t4 to synchronize its local timing reference to the master's timing reference.†

Most of the PTP implementation is done in the software above the UDP layer. However, the hardware support is required to capture the exact time when specific PTP packets enter or leave the Ethernet port at the PHY interface. This timing information must be captured and returned to the software for the proper implementation of PTP with high accuracy.†

The EMAC is intended to support IEEE 1588 operation in all modes with a resolution of one. When the two EMACs are operating in an IEEE 1588 environment, the MPU subsystem is responsible for maintaining synchronization between the time counters internal to the two MACs.

The IEEE 1588 interface to the FPGA allows the FPGA to provide a source for the emac_ptp_ref_clk input as well to allow it to monitor the pulse per second output from each EMAC controller.

The EMAC component provides a hardware assisted implementation of the IEEE 1588 protocol. Hardware support is for timestamp maintenance. Timestamps are updated when receiving any frame on the PHY interface and the receive descriptor is updated with this value. Timestamps are also updated when the SFD of a frame is transmitted and updates the transmit descriptor accordingly.†

EMAC to FPGA IEEE1588 Timestamp Interface

Table 17-4: EMAC to FPGA IEEE1588 Timestamp Interface

Signal Name		In/Out	Width	Description
f2h_emac_ptp_ref_clk	Timestamp Precision Time Protocol	In	1	Timestamp PTP Clock reference from the FPGA. Used as PTP clock reference for each EMAC when the FPGA has implemented timestamp capture interface. Common for all three EMACs.
ptp_pps_o	Pulse Per Second	Out	1	This signal is asserted based on the PPS mode selected in the Register 459 (PPS Control Register). Otherwise, this pulse signal is asserted every time the seconds counter is incremented. Synchronous to f2h_emac_f2hptp_ref_clk. Can only be sampled if FPGA clock is used as timestamp reference.
ptp_aux_ts_trig_i	Auxiliary Timestamp Trigger.	In	1	This signal is asserted to take an auxiliary snapshot of the time and store it in the 4-deep auxiliary timestamp FIFO. A rising edge on this port is used to trigger the auxiliary snapshot. The signal is synchronized internally with clk_ptp_ref_i which results in an additional delay of three cycles.

Reference Timing Source

To get a snapshot of the time, the EMAC takes the reference clock input and uses it to generate the reference time (64-bit) internally and capture timestamps.†

System Time Register Module

The 64-bit time is maintained in this module and updated using the input reference clock, osc1_clk. The osc1_clk clock comes from the clock manager and the emac_ptp_ref_clk clock comes from the FPGA fabric. This time is the source for taking snapshots (timestamps) of Ethernet frames being transmitted or received at the PHY interface.

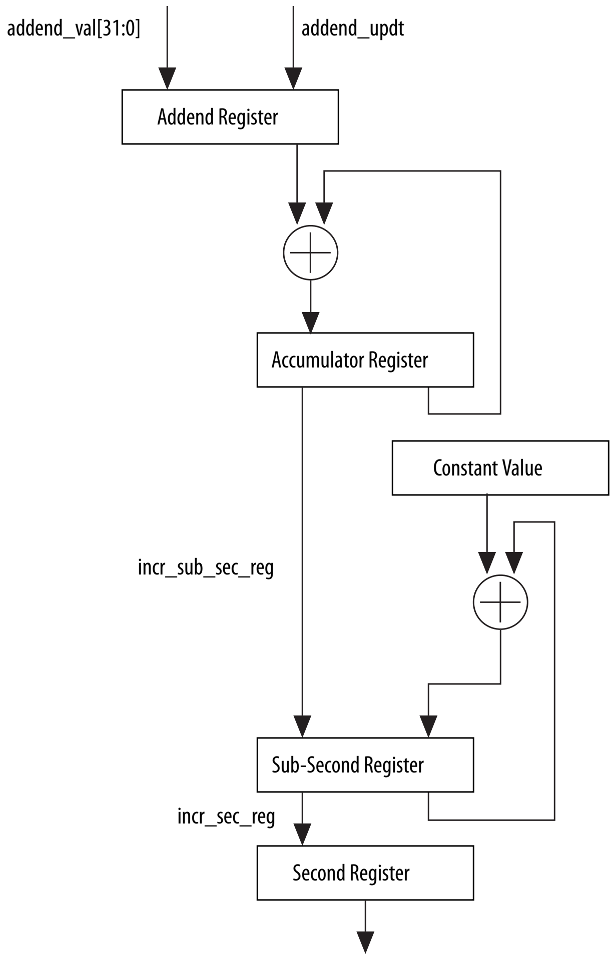
The system time counter can be initialized or corrected using the coarse correction method. In this method, the initial value or the offset value is written to the Timestamp Update register. For initialization, each EMAC's system time counter is written with the value in the Timestamp Update registers, while for system time correction, the offset value is added to or subtracted from the system time.

In the fine correction method, a slave clock's frequency drift with respect to the master clock is corrected over a period of time instead of in one clock, as in coarse correction. This helps maintain linear time and does not introduce drastic changes (or a large jitter) in the reference time between PTP sync message intervals.†

In this method, an accumulator sums up the contents of the Timestamp_Addend register, as shown in the figure below. The arithmetic carry that the accumulator generates is used as a pulse to increment the system time counter. The accumulator and the addend are 32-bit registers. Here, the accumulator acts as a high-precision frequency multiplier or divider.

Note: You must connect a PTP clock with a frequency higher than the frequency required for the specified accuracy.†

Figure 17-4: Algorithm for System Time Update Using Fine Method



The System Time Update logic requires a 50 MHz clock frequency to achieve 20-ns accuracy. The frequency division ratio (FreqDivisionRatio) is the ratio of the reference clock frequency to the required clock frequency. Hence, if the reference clock (clk_ptp_ref_i) is, for example, 66 MHz, this ratio is calculated as 66 MHz / 50 MHz = 1.32. Hence, the default addend value to be set in the register is 232 / 1.32, 0xC1F07C1F.

If the reference clock drifts lower, to 65 MHz for example, the ratio is 65 / 50, or 1.3 and the value to set in the addend register is 232 / 1.30, or 0xC4EC4EC4. If the clock drifts higher, to 67 MHz for example, the addend register must be set to 0xBF0B7672. When the clock drift is nil, the default addend value of 0xC1F07C1F (232 / 1.32) must be programmed.†

In the above figure, the constant value used to accumulate the sub-second register is decimal 43, which achieves an accuracy of 20 ns in the system time (in other words, it is incremented in 20-ns steps).

The software must calculate the drift in frequency based on the Sync messages and update the Addend register accordingly.†

Initially, the slave clock is set with `FreqCompensationValue0` in the Addend register. This value is as follows:†

```
FreqCompensationValue0 = 232 / FreqDivisionRatio†
```

If MasterToSlaveDelay is initially assumed to be the same for consecutive sync messages, the algorithm described below must be applied. After a few sync cycles, frequency lock occurs. The slave clock can then determine a precise MasterToSlaveDelay value and re-synchronize with the master using the new value.†

The algorithm is as follows:†

- At time $\mathtt{MasterSyncTime}_n$ the master sends the slave clock a sync message. The slave receives this message when its local clock is $\mathtt{SlaveClockTime}_n$ and computes $\mathtt{MasterClockTime}_n$ as:†

  $$\mathtt{MasterClockTime}_n = \mathtt{MasterSyncTime}_n + \mathtt{MasterToSlaveDelay}_n$$ †

- The master clock count for current sync cycle, $\mathtt{MasterClockCount}_n$ is given by:†

  $$\mathtt{MasterClockCount}_n = \mathtt{MasterClockTime}_n - \mathtt{MasterClockTime}_{n-1} \texttt{ (assuming that MasterToSlaveDelay is the same for sync cycles n and n - 1)}$$ †

- The slave clock count for current sync cycle, $\mathtt{SlaveClockCount}_n$ is given by:†

  $$\mathtt{SlaveClockCount}_n = \mathtt{SlaveClockTime}_n - \mathtt{SlaveClockTime}_{n-1}$$ †

- The difference between master and slave clock counts for current sync cycle, $\mathtt{ClockDiffCount}_n$ is given by:†

  $$\mathtt{ClockDiffCount}_n = \mathtt{MasterClockCount}_n - \mathtt{SlaveClockCount}_n$$ †

- The frequency-scaling factor for slave clock, $\mathtt{FreqScaleFactor}_n$ is given by:†

  $$\mathtt{FreqScaleFactor}_n = (\mathtt{MasterClockCount}_n + \mathtt{ClockDiffCount}_n) / \mathtt{SlaveClockCount}_n$$ †

- The frequency compensation value for Addend register, $\mathtt{FreqCompensationValue}_n$ is given by: †

  $$\mathtt{FreqCompensationValue}_n = \mathtt{FreqScaleFactor}_n \times \mathtt{FreqCompensationValue}_{n-1} - 1$$ †

In theory, this algorithm achieves lock in one Sync cycle; however, it may take several cycles, because of changing network propagation delays and operating conditions.†

This algorithm is self-correcting: if for any reason the slave clock is initially set to a value from the master that is incorrect, the algorithm corrects it at the cost of more Sync cycles.†

Transmit Path Functions

The MAC captures a timestamp when the SFD of a frame is sent on the PHY interface. The frames for which you want to capture timestamps are controllable on a per-frame basis. In other words, each transmit frame can be marked to indicate whether a timestamp should be captured for that frame. The MAC does not process the transmitted frames to identify the PTP frames. You need to specify the frames for which you want to capture timestamps. The MAC returns the timestamp, along with the Transmit status of the frame, to hardware implemented in the FPGA. You can use the control bits in the transmit descriptor. The MAC returns the timestamp to the software inside the corresponding transmit descriptor, thus connecting the timestamp automatically to the specific PTP frame.†

Receive Path Functions

The MAC captures the timestamp of all frames received on the PHY interface. The DMA returns the timestamp to the software in the corresponding receive descriptor. The timestamp is written only to the last receive descriptor.†

Timestamp Error Margin

According to the IEEE 1588 specifications, a timestamp must be captured at the SFD of the transmitted and received frames at the PHY interface. Because the PHY interface receive and transmit clocks are not synchronous to the reference timestamp clock (osc1_clk) a small amount of drift is introduced when a timestamp is moved between asynchronous clock domains. In the transmit path, the captured and reported timestamp has a maximum error margin of two PTP clocks. It means that the captured timestamp has the reference timing source value that is given within two clocks after the SFD is transmitted on the PHY interface.

Similarly, in the receive path, the error margin is three PHY interface clocks, plus up to two PTP clocks. You can ignore the error margin because of the PHY interface clocks by assuming that this constant delay is present in the system (or link) before the SFD data reaches the PHY interface of the MAC.†

Frequency Range of Reference Timing Clock

The timestamp information is transferred across asynchronous clock domains, that is, from MAC clock domain to the FPGA clock domain. Therefore, a minimum delay is required between two consecutive timestamp captures. This delay is four clock cycles of the PHY interface and three clock cycles of PTP clocks. If the delay between two timestamp captures is less than this delay, the MAC does not take a timestamp snapshot for the second frame.

The maximum PTP clock frequency is limited by the maximum resolution of the reference time (20 ns resulting in 50 MHz) and the timing constraints achievable for logic operating on the PTP clock. In addition, the resolution, or granularity, of the reference time source determines the accuracy of the synchronization. Therefore, a higher PTP clock frequency gives better system performance.†

The minimum PTP clock frequency depends on the time required between two consecutive SFD bytes. Because the PHY interface clock frequency is fixed by the IEEE 1588 specification, the minimum PTP clock frequency required for proper operation depends upon the operating mode and operating speed of the MAC.†

Table 17-5: Minimum PTP Clock Frequency Example

Mode	Minimum Gap Between Two SFDs	Minimum PTP Frequency
100-Mbps full-duplex operation	168 MII clocks (128 clocks for a 64-byte frame + 24 clocks of min IFG + 16 clocks of preamble)	(3 * PTP) + (4 * MII) <= 168 * MII, that is, ~0.5 MHz (168 – 4) * 40 ns ÷ 3 = 2180 ns period)
1000-Mbps half duplex operation	24 GMII clocks (4 for a jam pattern sent just after SFD because of collision + 12 IFG + 8 preamble)	(3 * PTP) + 4 * GMII <= 24 * GMII, that is, 18.75 MHz

Related Information

IEEE 1588-2008 Advanced Timestamps

In addition to the basic timestamp features mentioned in IEEE 1588-2002 Timestamps, the EMAC supports the following advanced timestamp features defined in the IEEE 1588-2008 standard.†

- Supports the IEEE 1588-2008 (version 2) timestamp format. †
- Provides an option to take a timestamp of all frames or only PTP type frames. †
- Provides an option to take a timestamp of only event messages. †
- Provides an option to take the timestamp based on the clock type: ordinary, boundary, end-to-end, or peer-to-peer. †
- Provides an option to configure the EMAC to be a master or slave for ordinary and boundary clock. †
- Identifies the PTP message type, version, and PTP payload in frames sent directly over Ethernet and sends the status. †
- Provides an option to measure sub-second time in digital or binary format. †

Related Information

http://standards.ieee.ort/findstds/index.html
For more information about advanced timestamp features, refer to the *IEEE Standard 1588 - 2008 IEEE Standard for a Precision Clock Synchronization Protocol for Networked Measurement and Control System, available on the IEEE Standards Association website.*

Peer-to-Peer PTP Transparent Clock (P2P TC) Message Support

The IEEE 1588-2008 version supports Peer-to-Peer PTP (Pdelay) messages in addition to SYNC, Delay Request, Follow-up, and Delay Response messages.†

Clock Types

The EMAC supports the following clock types defined in the IEEE 1588-2008 standard:

- Ordinary clock†
- Boundary clock†
- End-to-End transparent clock†
- Peer-to-Peer transparent clock†

Reference Timing Source

The EMAC supports the following reference timing source features defined in the IEEE 1588-2008 standard:

- 48-bit seconds Field†
- Fixed pulse-per-second output†
- Flexible pulse-per-second output†
- Auxiliary snapshots (timestamps) with external events

Transmit Path Functions

The advanced timestamp feature is supported through the descriptors format.

Receive Path Functions

The MAC processes the received frames to identify valid PTP frames. You can control the snapshot of the time, to be sent to the application, by using the following options:†

- Enable timestamp for all frames.†
- Enable timestamp for IEEE 1588 version 2 or version 1 timestamp.†
- Enable timestamp for PTP frames transmitted directly over Ethernet or UDP/IP Ethernet.†
- Enable timestamp snapshot for the received frame for IPv4 or IPv6.†
- Enable timestamp snapshot for EVENT messages (SYNC, DELAY_REQ, PDELAY_REQ, or PDELAY_RESP) only.†
- Enable the node to be a master or slave and select the timestamp type. This controls the type of messages for which timestamps are taken.†

The DMA returns the timestamp to the software inside the corresponding transmit or receive descriptor.

Auxiliary Snapshot

The auxiliary snapshot feature allows you to store a snapshot (timestamp) of the system time based on an external event. The event is considered to be the rising edge of the sideband signal ptp_aux_ts_trig_i. One auxiliary snapshot input is available. The depth of the auxiliary snapshot FIFO buffer is 16.

The timestamps taken for any input are stored in a common FIFO buffer. The host can read a register to know which input's timestamp is available for reading at the top of this FIFO buffer. The MAC stores these timestamps in a FIFO buffer. Only 64 bits of the timestamp are stored in the FIFO buffer. When a timestamp is stored, the MAC indicates this to the host with an interrupt. The value of the timestamp is read through a FIFO buffer register access. †

IEEE 802.3az Energy Efficient Ethernet

Energy Efficient Ethernet (EEE) standardized by IEEE 802.3-az, version D2.0 is supported by the EMAC. It is supported by the MAC operating in 10/100/1000 Mbps rates. EEE is only supported when the EMAC is configured to operate with the RGMII PHY interface operating in full-duplex mode. It does not support half-duplex mode.

EEE enables the MAC to operate in Low-Power Idle (LPI) mode. Either end point of an Ethernet link can disable functionality to save power during periods of low link utilization. The MAC controls whether the system should enter or exit LPI mode and communicates this to the PHY.†

Related Information

http://www.ieee802.org/3/
For details about the *IEEE 802.3az Energy Efficient Ethernet standard*, refer to the IEEE 802.3 Ethernet Working Group website.†

LPI Timers

Two timers internal to the EMAC are associated with LPI mode:

- LPI Link Status (LS) Timer†
- LPI TW Timer†

The LPI LS timer counts, in ms, the time expired since the link status is up. This timer is cleared every time the link goes down and is incremented when the link is up again and the terminal count as programmed by the software is reached. The PHY interface does not assert the LPI pattern unless the terminal count is reached. This ensures a minimum time for which no LPI pattern is asserted after a link is established with the remote station. This period is defined as one second in the IEEE standard 802.3-az, version D2.0. The LPI LS timer is 10 bits wide. Therefore, the software can program up to 1023 ms.†

The LPI TW timer counts, in µs, the time expired since the deassertion of LPI. The terminal count of the timer is the value of resolved transmit TW that is the auto-negotiated time after which the MAC can resume the normal transmit operation. The MAC supports the LPI TW timer in units of µs. The LPI TW timer is 16 bits wide. Therefore, the software can program up to 65535 µs.†

The EMAC generates the LPI interrupt when the transmit or receive channel enters or exits the LPI state.†

Checksum Offload

Communication protocols such as TCP and UDP implement checksum fields, which help determine the integrity of data transmitted over a network. Because the most widespread use of Ethernet is to encapsulate TCP and UDP over IP datagrams, the EMAC has a Checksum Offload Engine (COE) to support checksum calculation and insertion in the transmit path, and error detection in the receive path. Supported offloading types:

- Transmit IP header checksum†
- Transmit TCP/UDP/ICMP checksum†
- Receive IP header checksum†
- Receive full checksum†

Frame Filtering

The EMAC implements the following types of filtering for receive frames.

Source Address or Destination Address Filtering

The Address Filtering Module checks the destination and source address field of each incoming packet.†

Unicast Destination Address Filter

Up to 128 MAC addresses for unicast perfect filtering are supported. The filter compares all 48 bits of the received unicast address with the programmed MAC address for any match. Default MacAddr0 is always enabled, other addresses MacAddr1–MacAddr127 are selected with an individual enable bit. For MacAddr1–MacAddr31 addresses, you can mask each byte during comparison with the corresponding received DA byte. This enables group address filtering for the DA. The MacAddr32-MacAddr127 addresses do not have mask control and all six bytes of the MAC address are compared with the received six bytes of DA.†

In hash filtering mode, the filter performs imperfect filtering for unicast addresses using a 256-bit hash table. It uses the upper ten bits of the CRC of the received destination address to index the content of the hash table. A value of 0 selects Bit 0 of the selected register, and a value of 111111 binary selects Bit 63 of the Hash Table register. If the corresponding bit is set to one, the unicast frame is said to have passed the hash filter; otherwise, the frame has failed the hash filter.†

Multicast Destination Address Filter

The MAC can be programmed to pass all multicast frames. In Perfect Filtering mode, the multicast address is compared with the programmed MAC Destination Address registers (1–31). Group address filtering is also supported. In hash filtering mode, the filter performs imperfect filtering using a 256-bit hash table. For hash filtering, it uses the upper ten bits of the CRC of the received multicast address to index the contents of the hash table. A value of 0 selects Bit 0 of the selected register and a value of 111111 binary selects Bit 63 of the Hash Table register. If the corresponding bit is set to one, then the multicast frame is said to have passed the hash filter; otherwise, the frame has failed the hash filter.†

Hash or Perfect Address Filter

The filter can be configured to pass a frame when its DA matches either the hash filter or the Perfect filter. This configuration applies to both unicast and multicast frames.†

Broadcast Address Filter

The filter does not filter any broadcast frames in the default mode. However, if the MAC is programmed to reject all broadcast frames, the filter drops any broadcast frame.†

Unicast Source Address Filter

The MAC can also perform a perfect filtering based on the source address field of the received frames. Group filtering with SA is also supported. You can filter a group of addresses by masking one or more bytes of the address.†

Inverse Filtering Operation (Invert the Filter Match Result at Final Output)

For both Destination and Source address filtering, there is an option to invert the filter-match result at the final output. The result of the unicast or multicast destination address filter is inverted in this mode.†

VLAN Filtering

The EMAC supports the two kinds of VLAN filtering:

- VLAN tag-based filtering†
- VLAN hash filtering†

VLAN Tag-Based Filtering

In the VLAN tag-based frame filtering, the MAC compares the VLAN tag of the received frame and provides the VLAN frame status to the application. Based on the programmed mode, the MAC compares the lower 12 bits or all 16 bits of the received VLAN tag to determine the perfect match. If VLAN tag filtering is enabled, the MAC forwards the VLAN-tagged frames along with VLAN tag match status and drops the VLAN frames that do not match. You can also enable the inverse matching for VLAN frames. In addition, you can enable matching of SVLAN tagged frames along with the default Customer Virtual Local Area Network (C-VLAN) tagged frames.†

VLAN Hash Filtering with a 16-Bit Hash Table

The MAC provides VLAN hash filtering with a 16-bit hash table. The MAC also supports the inverse matching of the VLAN frames. In inverse matching mode, when the VLAN tag of a frame matches the perfect or hash filter, the packet should be dropped. If the VLAN perfect and VLAN hash match are enabled, a frame is considered as matched if either the VLAN hash or the VLAN perfect filter matches. When inverse match is set, a packet is forwarded only when both perfect and hash filters indicate mismatch.†

Layer 3 and Layer 4 Filters

Layer 3 filtering refers to source address and destination address filtering. Layer 4 filtering refers to source port and destination port filtering. The frames are filtered in the following ways:†

- Matched frames†
- Unmatched frames†
- Non-TCP or UDP IP frames†

Matched Frames

The MAC forwards the frames, which match all enabled fields, to the application along with the status. The MAC gives the matched field status only if one of the following conditions is true:†

- All enabled Layer 3 and Layer 4 fields match.†
- At least one of the enabled field matches and other fields are bypassed or disabled.†

Using the CSR set, you can define up to four filters, identified as filter 0 through filter 3. When multiple Layer 3 and Layer 4 filters are enabled, any filter match is considered as a match. If more than one filter matches, the MAC provides status of the lowest filter with filter 0 being the lowest and filter 3 being the highest. For example, if filter 0 and filter 1 match, the MAC gives the status corresponding to filter 0.†

Unmatched Frames

The MAC drops the frames that do not match any of the enabled fields. You can use the inverse match feature to block or drop a frame with specific TCP or UDP over IP fields and forward all other frames. You can configure the EMAC so that when a frame is dropped, it receives a partial frame with appropriate abort status or drops it completely.†

NonTCP or UDP IP Frames

By default, all non-TCP or UDP IP frames are bypassed from the Layer 3 and Layer 4 filters. You can optionally program the MAC to drop all non-TCP or UDP over IP frames.†

Clocks and Resets

Table 17-6: Ethernet MAC Controller Clocks

Name	Nominal Frequency	Functional Usage	Notes
clk_ref_i	250 Mhz	Reference Clock to the EMAC	If supplied from clock interface, clock is emac0_clk or emac1_clk
clk_tx_i	125/25/2.5 MHz	Auto negotiates speed down to 10/100 Mbps	
clk_rx_i		PHY provides this reference to MAC	All PHY signals received by the MAC are synchronous to this clock

Clock Gating for EEE

For the RGMII PHY interface, you can gate the transmit clock for Energy Efficient Ethernet (EEE) applications.

Related Information

Programming Guidelines for Energy Efficient Ethernet on page 17-57

Resets

Table 17-7: Ethernet MAC Controller Reset Signals

Name	Functional Usage	Notes
rst_clk_tx_n_o	Transmit clock reset output	Used to reset external PHY transmit clock domain logic
rst_clk_rx_n_o	Receive clock reset output	Used to reset external PHY receive clock domain logic

Interrupts

Interrupts are generated as a result of specific events in the EMAC and external PHY device. The interrupt status register indicates all conditions which may trigger an interrupt and the interrupt enable register determines which interrupts can propagate.

Ethernet MAC Programming Model

DMA Controller

The DMA has independent transmit and receive engines, and a CSR space. The transmit engine transfers data from system memory to the device port or MAC transaction layer (MTL), while the receive engine transfers data from the device port to the system memory. The controller use descriptors to efficiently move data from source to destination with minimal Host CPU intervention. The DMA is designed for packet-oriented data transfers such as frames in Ethernet. The controller can be programmed to interrupt the Host CPU for situations such as frame transmit and receive transfer completion, and other normal/ error conditions.

The DMA and the Host driver communicate through two data structures:†

- Control and Status registers (CSR)†
- Descriptor lists and data buffers †

Descriptor Lists and Data Buffers†

The DMA transfers data frames received by the MAC to the receive Buffer in the Host memory, and transmit data frames from the transmit Buffer in the Host memory. Descriptors that reside in the Host memory act as pointers to these buffers.†

There are two descriptor lists: one for reception and one for transmission. The base address of each list is written into Register 3 (Receive Descriptor List Address Register) and Register 4 (Transmit Descriptor List Address Register), respectively. A descriptor list is forward linked (either implicitly or explicitly). The last descriptor may point back to the first entry to create a ring structure. Explicit chaining of descriptors is accomplished by setting the second address chained in both receive and transmit descriptors (RDES1[24] and TDES1[24]). The descriptor lists resides in the Host physical memory address space. Each descriptor can point to a maximum of two buffers. This enables two buffers to be used, physically addressed, rather than contiguous buffers in memory.†

A data buffer resides in the Host physical memory space, and consists of an entire frame or part of a frame, but cannot exceed a single frame. Buffers contain only data, buffer status is maintained in the descriptor. Data chaining refers to frames that span multiple data buffers. However, a single descriptor cannot span multiple frames. The DMA skips to the next frame buffer when end-of-frame is detected. Data chaining can be enabled or disabled.†

Figure 17-5: Descriptor Ring Structure

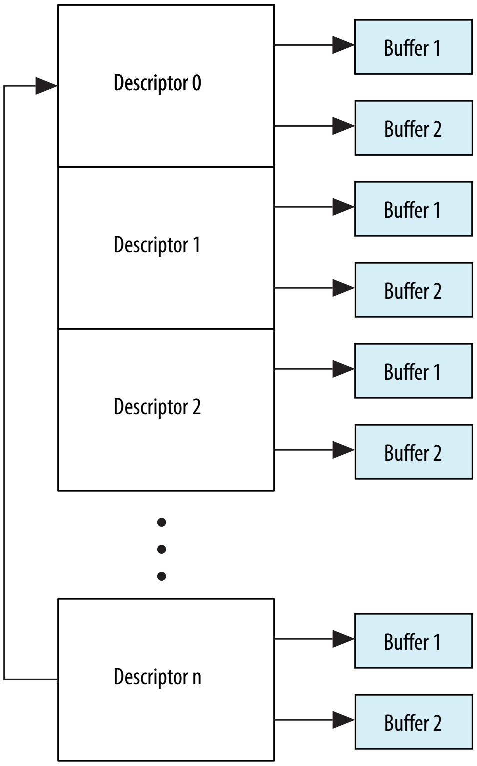

Figure 17-6: Descriptor Chain Structure

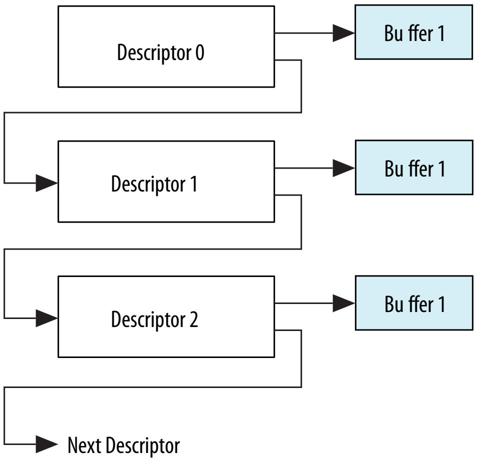

Note: You can select a descriptor structure during RTL configuration. The control bits in the descriptor structure are assigned so that the application can use an 8 KB buffer. All descriptions refer to the default descriptor structure.

Initialization for the EMAC

1. Write to Register 0 (Bus Mode Register) to set Host bus access parameters. †
2. Write to Register 7 (Interrupt Enable Register) to mask unnecessary interrupt causes. †
3. Create the transmit and receive descriptor lists, and then write to DMA Register 3 (Receive Descriptor List Address Register) and Register 4 (Transmit Descriptor List Address Register), providing the DMA with the starting address of each list. †
4. Write to Register 1 (MAC Frame Filter), Register 2 (Hash Table High Register), and Register 3 (Hash Table Low Register) for desired filtering options. †
5. Write to Register 1 (MAC Frame Filter) to configure the operating mode and enable the transmit operation (Bit 3: Transmitter Enable). The PS and DM bits are set based on the auto-negotiation result (read from the PHY). †
6. Write to Register 6 (Operation Mode Register) to set Bits 13 and 1 to start transmission and reception. †
7. Write to Register 0 (MAC Configuration Register) to enable the receive operation (Bit 2: Receiver Enable). †

The transmit and receive engines enter the Running state and attempt to acquire descriptors from the respective descriptor lists. The receive and transmit engines then begin processing receive and transmit operations. The transmit and receive processes are independent of each other and can be started or stopped separately. †

Host Bus Burst Access

The DMA attempts to execute fixed-length Burst transfers on the master interface if configured to do so through FB bit of Register 0 (Bus Mode Register). The maximum Burst length is indicated and limited by the PBL field (Bits [13:8]) Register 0 (Bus Mode Register). The receive and transmit descriptors are always accessed in the maximum possible (limited by PBL or 16 * 8/bus width) burst-size for the 16- bytes to be read.

The transmit DMA initiates a data transfer only when sufficient space to accommodate the configured burst is available in MTL transmit FIFO buffer or the number of bytes till the end of frame (when it is less than the configured burst-length). The DMA indicates the start address and the number of transfers required to the master interface. When the interface is configured for fixed-length burst, then it transfers data using the best combination of INCR4, 8, or 16 and SINGLE transactions. Otherwise (no fixed-length burst), it transfers data using INCR (undefined length) and SINGLE transactions.

The receive DMA initiates a data transfer only when sufficient data to accommodate the configured burst is available in MTL receive FIFO buffer or when the end of frame (when it is less than the configured burst-length) is detected in the receive FIFO buffer. The DMA indicates the start address and the number of transfers required to the master interface. When the interface is configured for fixed-length burst, then it transfers data using the best combination of INCR4, 8, or 16 and SINGLE transactions. If the end-of frame is reached before the fixed-burst ends on the interface, then dummy transfers are performed in order to complete the fixed-burst. Otherwise (FB bit of Register 0 (Bus Mode Register) is reset), it transfers data using INCR (undefined length) and SINGLE transactions.

When the interface is configured for address-aligned beats, both DMA engines ensure that the first burst transfer initiated is less than or equal to the size of the configured PBL. Thus, all subsequent beats start at an address that is aligned to the configured PBL. The DMA can only align the address for beats up to size 16 (for PBL > 16), because the interface does not support more than INCR16.

Host Data Buffer Alignment

The transmit and receive data buffers do not have any restrictions on start address alignment. For example, in systems with 32-bit memory, the start address for the buffers can be aligned to any of the four bytes. However, the DMA always initiates transfers with address aligned to the bus width with dummy data for the byte lanes not required. This typically happens during the transfer of the beginning or end of an Ethernet frame. The software driver should discard the dummy bytes based on the start address of the buffer and size of the frame.†

Example: Buffer Read

If the transmit buffer address is 0x00000FF2 (for 32-bit data bus), and 15 bytes need to be transferred, then the DMA reads five full words from address 0x00000FF0, but when transferring data to the MTL transmit FIFO buffer, the extra bytes (the first two bytes) are dropped or ignored. Similarly, the last 3 bytes of the last transfer are also ignored. The DMA always ensures it transfers a full 32-bit data to the MTL transmit FIFO buffer, unless it is the end-of-frame.

Example: Buffer Write

If the receive buffer address is 0x0000FF2 (for 64-bit data bus) and 16 bytes of a received frame need to be transferred, then the DMA writes 3 full words from address 0x00000FF0. But the first 2 bytes of first transfer and the last 6 bytes of the third transfer have dummy data.

Buffer Size Calculations

The DMA does not update the size fields in the transmit and receive descriptors. The DMA updates only the status fields (RDES and TDES) of the descriptors. The driver has to perform the size calculations. †

The transmit DMA transfers the exact number of bytes (indicated by buffer size field of TDES1) towards the MAC. If a descriptor is marked as first (FS bit of TDES1 is set), then the DMA marks the first transfer from the buffer as the start of frame. If a descriptor is marked as last (LS bit of TDES1), then the DMA marks the last transfer from that data buffer as the end-of frame to the MTL. †

The receive DMA transfers data to a buffer until the buffer is full or the end-of frame is received from the MTL. If a descriptor is not marked as last (LS bit of RDES0), then the descriptor's corresponding buffer(s) are full and the amount of valid data in a buffer is accurately indicated by its buffer size field minus the data buffer pointer offset when the FS bit of that descriptor is set. The offset is zero when the data buffer pointer is aligned to the data bus width. If a descriptor is marked as last, then the buffer may not be full (as indicated by the buffer size in RDES1). To compute the amount of valid data in this final buffer, the driver must read the frame length (FL bits of RDES0[29:16]) and subtract the sum of the buffer sizes of the preceding buffers in this frame. The receive DMA always transfers the start of next frame with a new descriptor. †

Note: Even when the start address of a receive buffer is not aligned to the data width of system bus, the system should allocate a receive buffer of a size aligned to the system bus width. For example, if the system allocates a 1,024-byte (1 KB) receive buffer starting from address 0x1000, the software can program the buffer start address in the receive descriptor to have a 0x1002 offset. The receive DMA writes the frame to this buffer with dummy data in the first two locations (0x1000 and 0x1001). The actual frame is written from location 0x1002. Thus, the actual useful space in this buffer is 1,022 bytes, even though the buffer size is programmed as 1,024 bytes, because of the start address offset. †

Transmission

Transmission functions use transmit descriptors.

Related Information

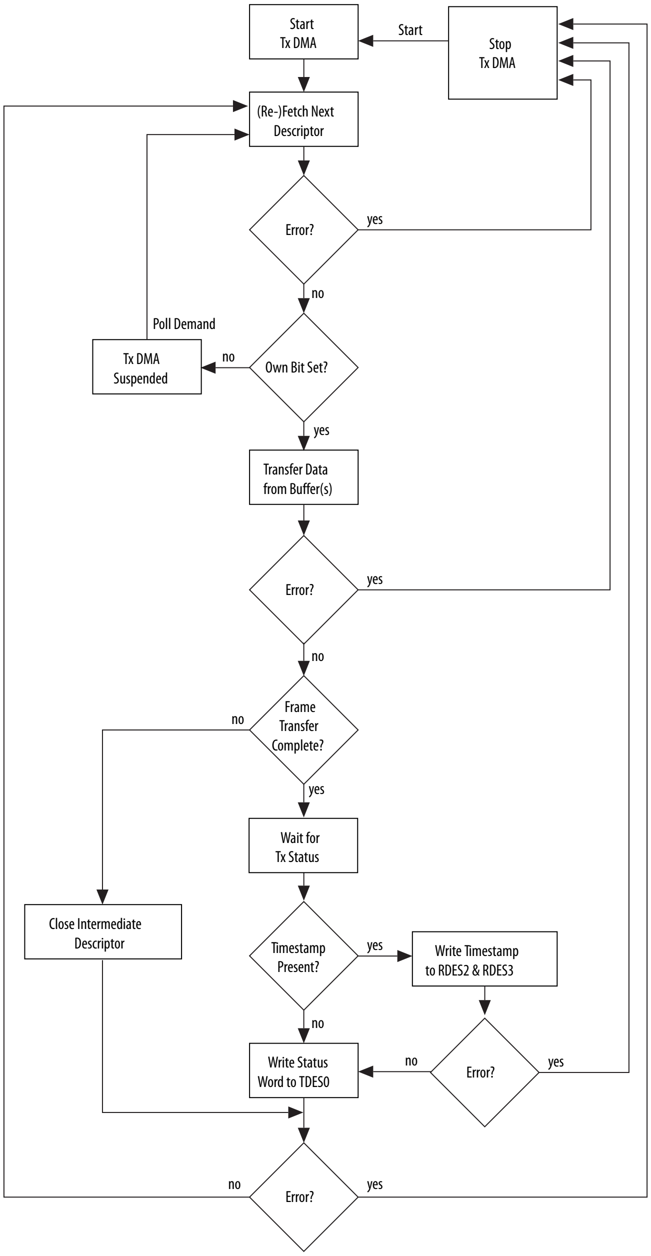
Transmit Descriptor on page 17-39

TX DMA Operation: Default (Non-OSF) Mode

The transmit DMA engine in default mode proceeds as follows: †

1. The Host sets up the transmit descriptor (TDES0-TDES3) and sets the Own bit (TDES0[31]) after setting up the corresponding data buffer(s) with Ethernet frame data. †
2. When Bit 13 (ST) of Register 6 (Operation Mode Register) is set, the DMA enters the Run state. †
3. While in the Run state, the DMA polls the transmit descriptor list for frames requiring transmission. After polling starts, it continues in either sequential descriptor ring order or chained order. If the DMA detects a descriptor flagged as owned by the Host (TDES0[31] = 0), or if an error condition occurs, transmission is suspended and both the Bit 2 (Transmit Buffer Unavailable) and Bit 16 (Normal Interrupt Summary) of the Register 5 (Status Register) are set. The transmit Engine proceeds to **step 9**.
4. If the acquired descriptor is flagged as owned by DMA (TDES0[31] = 1), the DMA decodes the transmit Data Buffer address from the acquired descriptor.
5. The DMA fetches the transmit data from the Host memory and transfers the data to the MTL for transmission. †
6. If an Ethernet frame is stored over data buffers in multiple descriptors, the DMA closes the intermediate descriptor and fetches the next descriptor. Repeat **step 3**, **step 4**, and **step 5** until the end-of-Ethernet-frame data is transferred to the MTL. †
7. When frame transmission is complete, if IEEE 1588 timestamping was enabled for the frame (as indicated in the transmit status) the timestamp value obtained from MTL is written to the transmit descriptor (TDES2 and TDES3) that contains the end-of-frame buffer. The status information is then written to this transmit descriptor (TDES0). Because the Own bit is cleared during this step, the Host now owns this descriptor. If timestamping was not enabled for this frame, the DMA does not alter the contents of TDES2 and TDES3. †
8. Bit 0 (Transmit Interrupt) of Register 5 (Status Register) is set after completing transmission of a frame that has Interrupt on Completion (TDES1[31]) set in its Last descriptor. The DMA engine then returns to **step 3**. †
9. In the Suspend state, the DMA tries to re-acquire the descriptor (and thereby return to **step 3**) when it receives a Transmit Poll demand and the Underflow Interrupt Status bit is cleared. †

Figure 17-7: TX DMA Operation in Default Mode



Related Information

TX DMA Operation: Default (Non-OSF) Mode on page 17-29

TX DMA Operation: OSF Mode

While in the Run state, the transmit process can simultaneously acquire two frames without closing the Status descriptor of the first [if Bit 2 (OSF) in Register 6 (Operation Mode Register) is set]. As the transmit process finishes transferring the first frame, it immediately polls the transmit descriptor list for the second frame. If the second frame is valid, the transmit process transfers this frame before writing the first frame's status information. †

In OSF mode, the Run state transmit DMA operates in the following sequence: †

1. The DMA operates as described in steps 1 - 6 of the **TX DMA Operation: Default (Non-OSF) Mode** on page 17-29 section.
2. Without closing the previous frame's last descriptor, the DMA fetches the next descriptor. †
3. If the DMA owns the acquired descriptor, the DMA decodes the transmit buffer address in this descriptor. If the DMA does not own the descriptor, the DMA goes into Suspend mode and skips to **step 7**.†
4. The DMA fetches the transmit frame from the Host memory and transfers the frame to the MTL until the End-of-frame data is transferred, closing the intermediate descriptors if this frame is split across multiple descriptors. †
5. The DMA waits for the previous frame's frame transmission status and timestamp. Once the status is available, the DMA writes the timestamp to TDES2 and TDES3, if such timestamp was captured (as indicated by a status bit). The DMA then writes the status, with a cleared Own bit, to the corresponding TDES0, thus closing the descriptor. If timestamping was not enabled for the previous frame, the DMA does not alter the contents of TDES2 and TDES3. †
6. If enabled, the transmit interrupt is set, the DMA fetches the next descriptor, then proceeds to **step 3** (when Status is normal). If the previous transmission status shows an underflow error, the DMA goes into Suspend mode (**step 7**). †
7. In Suspend mode, if a pending status and timestamp are received from the MTL, the DMA writes the timestamp (if enabled for the current frame) to TDES2 and TDES3, then writes the status to the corresponding TDES0. It then sets relevant interrupts and returns to Suspend mode. †
8. The DMA can exit Suspend mode and enter the Run state (go to **step 1** or **step 2** depending on pending status) only after receiving a Transmit Poll demand (Register 1 (Transmit Poll Demand Register). †

Note: As the DMA fetches the next descriptor in advance before closing the current descriptor, the descriptor chain should have more than two different descriptors for correct and proper operation. †

Transmit Frame Processing

The transmit DMA expects that the data buffers contain complete Ethernet frames, excluding preamble, pad bytes, and FCS fields. The DA, SA, and Type/Len fields contain valid data. If the transmit descriptor indicates that the MAC must disable CRC or PAD insertion, the buffer must have complete Ethernet frames (excluding preamble), including the CRC bytes. †

Frames can be data-chained and can span several buffers. Frames must be delimited by the First Descriptor (TDES1[29]) and the Last Descriptor (TDES1[30]), respectively. †

As transmission starts, the First Descriptor must have (TDES1[29]) set. When this occurs, frame data transfers from the Host buffer to the MTL transmit FIFO buffer. Concurrently, if the current frame has the Last Descriptor (TDES1[30]) clear, the transmit Process attempts to acquire the Next descriptor. The transmit Process expects this descriptor to have TDES1[29] clear. If TDES1[30] is clear, it indicates an intermediary buffer. If TDES1[30] is set, it indicates the last buffer of the frame. †

After the last buffer of the frame has been transmitted, the DMA writes back the final status information to the Transmit Descriptor 0 (TDES0) word of the descriptor that has the last segment set in Transmit Descriptor 1 (TDES1[30]). At this time, if Interrupt on Completion (TDES1[31]) is set, the Bit 0 (Transmit Interrupt) of Register 5 (Status Register) is set, the Next descriptor is fetched, and the process repeats. †

The actual frame transmission begins after the MTL transmit FIFO buffer has reached either a programmable transmit threshold (Bits [16:14] of Register 6 (Operation Mode Register)), or a full frame is contained in the FIFO buffer. There is also an option for Store and Forward Mode (Bit 21 of Register 6 (Operation Mode Register)). Descriptors are released (Own bit TDES0[31] clears) when the DMA finishes transferring the frame. †

Note: To ensure proper transmission of a frame and the next frame, you must specify a non-zero buffer size for the transmit descriptor that has the Last Descriptor (TDES1[30]) set. †

Transmit Polling Suspended

Transmit polling can be suspended by either of the following conditions: †

- The DMA detects a descriptor owned by the Host (TDES0[31]=0). To resume, the driver must give descriptor ownership to the DMA and then issue a Poll Demand command. †
- A frame transmission is aborted when a transmit error because of underflow is detected. The appropriate Transmit Descriptor 0 (TDES0) bit is set. †

If the DMA goes into SUSPEND state because of the first condition, then both Bit 16 (Normal Interrupt Summary) and Bit 2 (Transmit Buffer Unavailable) of Register 5 (Status Register) are set. If the second condition occur, both Bit 15 (Abnormal Interrupt Summary) and Bit 5 (Transmit Underflow) of Register 5 (Status Register) are set, and the information is written to Transmit Descriptor 0, causing the suspension. †

In both cases, the position in the transmit List is retained. The retained position is that of the descriptor following the Last descriptor closed by the DMA. †

The driver must explicitly issue a Transmit Poll Demand command after rectifying the suspension cause. †

Reception

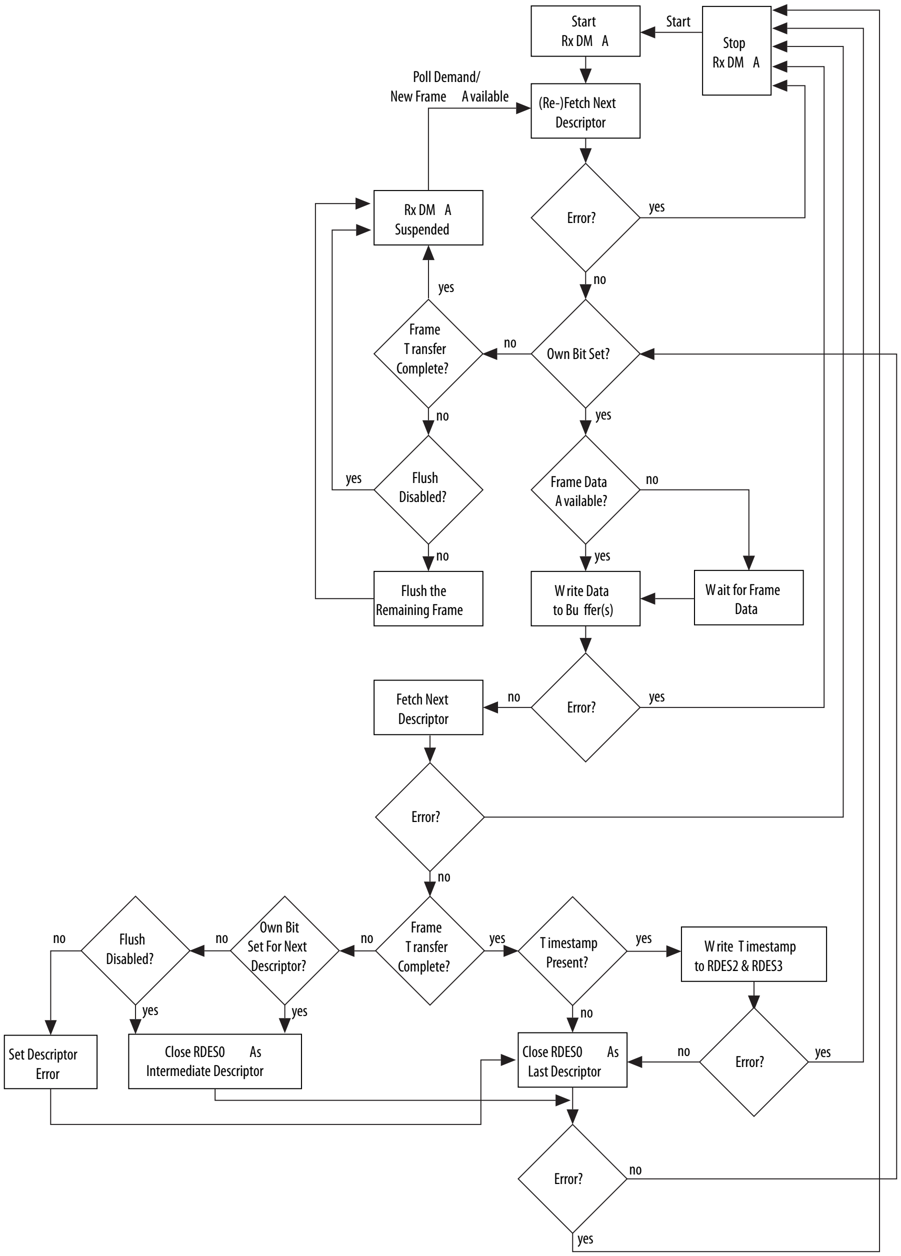
Receive functions use receive descriptors.

The receive DMA engine's reception sequence is depicted proceeds as follows:

1. The host sets up receive descriptors (RDES0-RDES3) and sets the Own bit (RDES0[31]).†
2. When Bit 1 (SR) of Register 6 (Operation Mode Register) is set, the DMA enters the Run state. While in the Run state, the DMA polls the receive descriptor list, attempting to acquire free descriptors. If the fetched descriptor is not free (is owned by the host), the DMA enters the Suspend state and jumps to step 9.†
3. The DMA decodes the receive data buffer address from the acquired descriptors.†
4. Incoming frames are processed and placed in the acquired descriptor's data buffers.†
5. When the buffer is full or the frame transfer is complete, the receive engine fetches the next descriptor.†

6. If the current frame transfer is complete, the DMA proceeds to **step 7**. If the DMA does not own the next fetched descriptor and the frame transfer is not complete (EOF is not yet transferred), the DMA sets the Descriptor Error bit in the RDES0 (unless flushing is disabled in Bit 24 of Register 6 (Operation Mode Register)). The DMA closes the current descriptor (clears the Own bit) and marks it as intermediate by clearing the Last Segment (LS) bit in the RDES0 value (marks it as Last Descriptor if flushing is not disabled), then proceeds to **step 8**. If the DMA does own the next descriptor but the current frame transfer is not complete, the DMA closes the current descriptor as intermediate and reverts to **step 4**.†
7. If IEEE 1588 timestamping is enabled, the DMA writes the timestamp (if available) to the current descriptor's RDES2 and RDES3. It then takes the receive frame's status from the MTL and writes the status word to the current descriptor's RDES0, with the Own bit cleared and the Last Segment bit set.†
8. The receive engine checks the latest descriptor's Own bit. If the host owns the descriptor (Own bit is 0), the Bit 7 (Receive Buffer Unavailable) of Register 5 (Status Register) is set and the DMA receive engine enters the Suspended state (Step 9). If the DMA owns the descriptor, the engine returns to **step 4** and awaits the next frame.
9. Before the receive engine enters the Suspend state, partial frames are flushed from the receive FIFO buffer. You can control flushing using Bit 24 of Register 6 (Operation Mode Register). †
10. The receive DMA exits the Suspend state when a Receive Poll demand is given or the start of next frame is available from the MTL's receive FIFO buffer. The engine proceeds to **step 2** and refetches the next descriptor. †

Figure 17-9: Receive DMA Operation



If software has enabled timestamping through CSR, when a valid timestamp value is not available for the frame (for example, because the receive FIFO buffer was full before the timestamp could be written to it), the DMA writes all-ones to RDES2 and RDES3. Otherwise (that is, if timestamping is not enabled), the RDES2 and RDES3 remain unchanged. †

Related Information

Receive Descriptor

Receive Descriptor Acquisition

The receive Engine always attempts to acquire an extra descriptor in anticipation of an incoming frame. Descriptor acquisition is attempted if any of the following conditions is satisfied: †

- Bit 1 (Start or Stop Receive) of Register 6 (Operation Mode Register) has been set immediately after being placed in the Run state. †
- The data buffer of current descriptor is full before the frame ends for the current transfer. †
- The controller has completed frame reception, but the current receive descriptor is not yet closed. †
- The receive process has been suspended because of a host-owned buffer (RDES0[31] = 0) and a new frame is received. †
- A Receive poll demand has been issued. †

Receive Frame Processing

The MAC transfers the received frames to the Host memory only when the frame passes the address filter and frame size is greater than or equal to configurable threshold bytes set for the receive FIFO buffer of MTL, or when the complete frame is written to the FIFO buffer in Store-and-Forward mode. †

If the frame fails the address filtering, it is dropped in the MAC block itself (unless Bit 31 (Receive All) of Register 1 (MAC Frame Filter) is set). Frames that are shorter than 64 bytes, because of collision or premature termination, can be removed from the MTL receive FIFO buffer. †

After 64 (configurable threshold) bytes have been received, the MTL block requests the DMA block to begin transferring the frame data to the receive Buffer pointed by the current descriptor. The DMA sets First Descriptor (RDES0[9]) after the DMA Host interface becomes ready to receive a data transfer (if DMA is not fetching transmit data from the host), to delimit the frame. The descriptors are released when the Own (RDES[31]) bit is reset to 0, either as the Data buffer fills up or as the last segment of the frame is transferred to the receive buffer. If the frame is contained in a single descriptor, both Last Descriptor (RDES[8]) and First Descriptor (RDES[9]) are set.

The DMA fetches the next descriptor, sets the Last Descriptor (RDES[8]) bit, and releases the RDES0 status bits in the previous frame descriptor. Then the DMA sets the Bit 6 (Receive Interrupt) of Register 5 (Status Register). The same process repeats unless the DMA encounters a descriptor flagged as being owned by the host. If this occurs, the receive Process sets the Bit 7 (Receive Buffer Unavailable) of Register 5 (Status Register) and then enters the Suspend state. The position in the receive list is retained. †

Receive Process Suspended

If a new receive frame arrives while the receive Process is in Suspend state, the DMA refetches the current descriptor in the Host memory. If the descriptor is now owned by the DMA, the receive Process re-enters the Run state and starts frame reception. If the descriptor is still owned by the host, by default, the DMA discards the current frame at the top of the MTL RX FIFO buffer and increments the missed frame counter. If more than one frame is stored in the MTL EX FIFO buffer, the process repeats. †

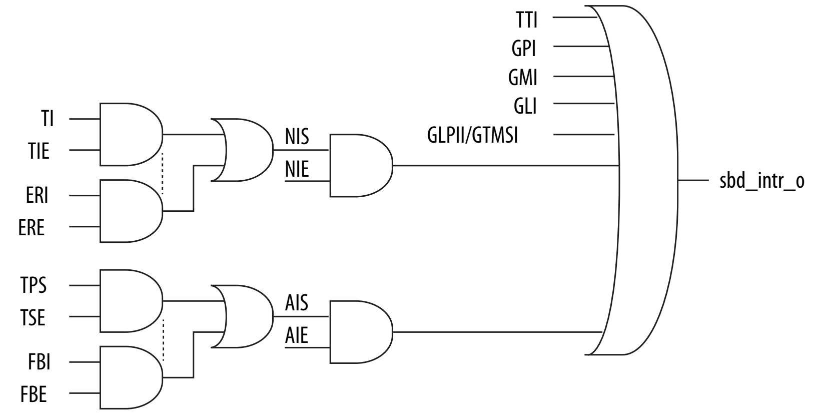
The discarding or flushing of the frame at the top of the MTL EX FIFO buffer can be avoided by disabling Flushing (Bit 24 of Register 6 (Operation Mode Register)). In such conditions, the receive process sets the Receive Buffer Unavailable status and returns to the Suspend state. †

Interrupts

Interrupts can be generated as a result of various events. The DMA Register 5 (Status Register) contains all the bits that might cause an interrupt. Register 7 (Interrupt Enable Register) contains an enable bit for each of the events that can cause an interrupt. †

There are two groups of interrupts, Normal and Abnormal, as described in Register 5 (Status Register). Interrupts are cleared by writing a 1 to the corresponding bit position. When all the enabled interrupts within a group are cleared, the corresponding summary bit is cleared. When both the summary bits are cleared, the sbd_intr_o interrupt signal is de-asserted. If the MAC is the cause for assertion of the interrupt, then any of the GLI, GMI, GPI, TTI, or GLPII bits of Register 5 (Status Register) are set high.

Figure 17-10: sbd_intr_o Generation[41]



Note: The Register 5 (Status Register) is the interrupt status register. The interrupt pin (sbd_intr_o) is asserted because of any event in this status register only if the corresponding interrupt enable bit is set in Register 7 (Interrupt Enable Register). †

Interrupts are not queued and if the interrupt event occurs before the driver has responded to it, no additional interrupts are generated. For example, Bit 6 (Receive Interrupt) of Register 5 (Status Register) indicates that one or more frames were transferred to the Host buffer. The driver must scan all descriptors, from the last recorded position to the first one owned by the DMA. †

An interrupt is generated only once for simultaneous, multiple events. The driver must scan the Register 5 (Status Register) for the cause of the interrupt. The interrupt is not generated again unless a new interrupting event occurs, after the driver has cleared the appropriate bit in Register 5 (Status Register). For example, the controller generates a Bit 6 (Receive Interrupt) of Register 5 (Status Register) and the driver begins reading Register 5 (Status Register). Next, Bit 7 (Receive Buffer Unavailable) of Register 5 (Status Register) occurs. The driver clears the receive interrupt. Even then, the sbd_intr_o signal is not de-asserted, because of the active or pending Receive Buffer Unavailable interrupt. †

Bits 7:0 (Interrupt Timer) of Register 9 (Receive Interrupt Watchdog Timer Register) is given for flexible control of receive Interrupt. When this Interrupt timer is programmed with a non-zero value, it gets activated as soon as the RX DMA completes a transfer of a received frame to system memory without asserting the receive Interrupt because it is not enabled in the corresponding Receive Descriptor (RDES1[31]. When this timer runs out as per the programmed value, RI bit is set and the interrupt is asserted if the corresponding RI is enabled in Register 7 (Interrupt Enable Register). This timer gets disabled before it runs out, when a frame is transferred to memory and the RI is set because it is enabled for that descriptor. †

[41] Signals NIS and AIS are registered.

Error Response to DMA

For any data transfer initiated by a DMA channel, if the slave replies with an error response, that DMA stops all operations and updates the error bits and the Fatal Bus Error bit in the Register 5 (Status Register). The DMA controller can resume operation only after soft resetting or hard resetting the EMAC and reinitializing the DMA.

Descriptor Overview

This section describes the HPS EMAC DMA descriptor.

The DMA in the Ethernet subsystem transfers data based on a single descriptor, as explained in DMA Controller. The descriptor is created in the system memory.

The descriptor format can have 8 DWORDS (32 bytes). The descriptor contains two buffers, two byte-count buffers, and two address pointers, which enable the adapter port to be compatible with various types of memory management schemes.

Related Information

- **DMA Controller** on page 17-25
- **Descriptors** on page 17-39
  Detailed bit map of the descriptor structure

Descriptor Endianness

The descriptor addresses must be aligned to the used bus width (Word for 32-bit bus). The data bus is configured as little-endian.

Related Information

Descriptors on page 17-39
Detailed bit map of the descriptor structure

Descriptors

The descriptor structure can have 8 DWORDS (32-bytes). The features of the descriptor structure are:

- The descriptor structure is implemented to support buffers of up to 8 KB (useful for Jumbo frames).
- There is a re-assignment of control and status bits in TDES0, TDES1, RDES0 (advanced timestamp or IPC full offload configuration), and RDES1. †
- The transmit descriptor stores the timestamp in TDES6 and TDES7 when you select the advanced timestamp. †
- This receive descriptor structure is also used for storing the extended status (RDES4) and timestamp (RDES6 and RDES7) when advanced timestamp, IPC Full Checksum Offload Engine, or Layer 3 and Layer 4 filter feature is selected. †
- You can select one of the following options for descriptor structure:
  - If timestamping is enabled in Register 448 (Timestamp Control Register) or Checksum Offload is enabled in Register 0 (MAC Configuration Register), the software needs to allocate 32-bytes (8 DWORDS) of memory for every descriptor. For this, the software should set Bit 7 (Descriptor Size) of Register 0 (Bus Mode Register).
  - If timestamping or Checksum Offload is not enabled, the extended descriptors (DES4 to DES7) are not required. Therefore, the software can use descriptors with the default size of 16 bytes (4 DWORDS). For this, the software should reset Bit 7 (Descriptor Size) of Register 0 (Bus Mode Register) to 0.
- When descriptor is selected without Timestamp or Receive IPC Full Checksum Offload Engine (Type 2) feature, the descriptor size is always 4 DWORDs (DES0-DES3). Therefore, the software can use descriptors with the default size of 16 bytes.

Transmit Descriptor

The application software must program the control bits TDES0[31:18] during the transmit descriptor initialization. When the DMA updates the descriptor, it writes back all the control bits except the OWN bit (which it clears) and updates the status bits[7:0].

With the advance timestamp support, the snapshot of the timestamp to be taken can be enabled for a given frame by setting Bit 25 (TTSE) of TDES0. When the descriptor is closed (that is, when the OWN bit is cleared), the timestamp is written into TDES6 and TDES7. This is indicated by the status Bit 17 (TTSS) of TDES0.

Note: When advanced timestamp feature is enabled, the software should set Bit 7 of Register 0 (Bus Mode Register), so that the DMA operates with extended descriptor size. When this control bit is reset, the TDES4-TDES7 descriptor space is not valid. †

Table 17-8: Transmit Descriptor Word 0 (TDES0)

Bit	Description
31	OWN: Own Bit When set, this bit indicates that the descriptor is owned by the DMA. When this bit is reset, it indicates that the descriptor is owned by the Host. The DMA clears this bit either when it completes the frame transmission or when the buffers allocated in the descriptor are read completely. The ownership bit of the frame's first descriptor must be set after all subsequent descriptors belonging to the same frame have been set. This avoids a possible race condition between fetching a descriptor and the driver setting an ownership bit. †
30	IC: Interrupt on Completion When set, this bit sets the Transmit Interrupt (Register 5[0]) after the present frame has been transmitted. †
29	LS: Last Segment When set, this bit indicates that the buffer contains the last segment of the frame. When this bit is set, the TBS1 or TBS2 field in TDES1 should have a non-zero value. †
28	FS: First Segment When set, this bit indicates that the buffer contains the first segment of a frame. †
27	DC: Disable CRC When this bit is set, the MAC does not append a CRC to the end of the transmitted frame. This is valid only when the first segment (TDES0[28]) is set. †

Bit	Description
26	DP: Disable Pad When set, the MAC does not automatically add padding to a frame shorter than 64 bytes. When this bit is reset, the DMA automatically adds padding and CRC to a frame shorter than 64 bytes, and the CRC field is added despite the state of the DC (TDES0[27]) bit. This is valid only when the first segment (TDES0[28]) is set. †
25	TTSE: Transmit Timestamp Enable When set, this bit enables IEEE1588 hardware timestamping for the transmit frame referenced by the descriptor. This field is valid only when the First Segment control bit (TDES0[28]) is set.
24	Reserved
23:22	CIC: Checksum Insertion Control. These bits control the checksum calculation and insertion. The following list describes the bit encoding: ▪ 0: Checksum Insertion Disabled. ▪ 1: Only IP header checksum calculation and insertion are enabled. ▪ 2: IP header checksum and payload checksum calculation and insertion are enabled, but pseudoheader checksum is not calculated in hardware. ▪ 3: IP Header checksum and payload checksum calculation and insertion are enabled, and pseudoheader checksum is calculated in hardware. This field is valid when the First Segment control bit (TDES0[28]) is set.
21	TER: Transmit End of Ring When set, this bit indicates that the descriptor list reached its final descriptor. The DMA returns to the base address of the list, creating a descriptor ring. †
20	TCH: Second Address Chained When set, this bit indicates that the second address in the descriptor is the Next descriptor address rather than the second buffer address. When TDES0[20] is set, TBS2 (TDES1[28:16]) is a "don't care" value. TDES0[21] takes precedence over TDES0[20]. †
19:18	Reserved
17	TTSS: Transmit Timestamp Status This field is used as a status bit to indicate that a timestamp was captured for the described transmit frame. When this bit is set, TDES2 and TDES3 have a timestamp value captured for the transmit frame. This field is only valid when the descriptor's Last Segment control bit (TDES0[29]) is set. †

Bit	Description
16	IHE: IP Header Error When set, this bit indicates that the MAC transmitter detected an error in the IP datagram header. The transmitter checks the header length in the IPv4 packet against the number of header bytes received from the application and indicates an error status if there is a mismatch. For IPv6 frames, a header error is reported if the main header length is not 40 bytes. Furthermore, the Ethernet Length/Type field value for an IPv4 or IPv6 frame must match the IPheader version received with the packet. For IPv4 frames, an error status is also indicated if the Header Length field has a value less than 0x5. †
15	ES: Error Summary Indicates the logical OR of the following bits: ▪ TDES0[14]: Jabber Timeout ▪ TDES0[13]: Frame Flush ▪ TDES0[11]: Loss of Carrier ▪ TDES0[10]: No Carrier ▪ TDES0[9]: Late Collision ▪ TDES0[8]: Excessive Collision ▪ TDES0[2]: Excessive Deferral ▪ TDES0[1]: Underflow Error ▪ TDES0[16]: IP Header Error ▪ TDES0[12]: IP Payload Error †
14	JT: Jabber Timeout When set, this bit indicates the MAC transmitter has experienced a jabber time-out. This bit is only set when Bit 22 (Jabber Disable) of Register 0 (MAC Configuration Register) is not set. †
13	FF: Frame Flushed When set, this bit indicates that the DMA or MTL flushed the frame because of a software Flush command given by the CPU. †
12	IPE: IP Payload Error When set, this bit indicates that MAC transmitter detected an error in the TCP, UDP, or ICMP IP datagram payload. The transmitter checks the payload length received in the IPv4 or IPv6 header against the actual number of TCP, UDP, or ICMP packet bytes received from the application and issues an error status in case of a mismatch. †

Bit	Description
11	LC: Loss of Carrier When set, this bit indicates that a loss of carrier occurred during frame transmission (that is, the gmii_crs_i signal was inactive for one or more transmit clock periods during frame transmission). This is valid only for the frames transmitted without collision when the MAC operates in the half-duplex mode. †
10	NC: No Carrier When set, this bit indicates that the Carrier Sense signal form the PHY was not asserted during transmission. †
9	Reserved
8	EC: Excessive Collision When set, this bit indicates that the transmission was aborted after 16 successive collisions while attempting to transmit the current frame. If Bit 9 (Disable Retry) bit in the Register 0 (MAC Configuration Register) is set, this bit is set after the first collision, and the transmission of the frame is aborted. †
7	VF: VLAN Frame When set, this bit indicates that the transmitted frame is a VLAN-type frame. †
6:3	CC: Collision Count (Status field) These status bits indicate the number of collisions that occurred before the frame was transmitted. This count is not valid when the Excessive Collisions bit (TDES0[8]) is set. The EMAC updates this status field only in the half-duplex mode.
2	ED: Excessive Deferral When set, this bit indicates that the transmission has ended because of excessive deferral of over 24,288 bit times (155,680 bits times in 1,000-Mbps mode or if Jumbo frame is enabled) if Bit 4 (Deferral Check) bit in Register 0 (MAC Configuration Register) is set high. †
1	UF: Underflow Error When set, this bit indicates that the MAC aborted the frame because the data arrived late from the Host memory. Underflow Error indicates that the DMA encountered an empty transmit buffer while transmitting the frame. The transmission process enters the Suspended state and sets both Transmit Underflow (Register 5[5]) and Transmit Interrupt (Register 5[0]). †
0	DB: Deferred Bit When set, this bit indicates that the MAC defers before transmission because of the presence of carrier. This bit is valid only in the half-duplex mode. †

Table 17-9: Transmit Descriptor Word 1 (TDES1)

Bit	Description
31:29	Reserved
28:16	TBS2: Transmit Buffer 2 Size This field indicates the second data buffer size in bytes. This field is not valid if TDES0[20] is set. †
15:13	Reserved †
12:0	TBS1: Transmit Buffer 1 Size These bits indicate the first data buffer byte size, in bytes. If this field is 0, the DMA ignores this buffer and uses Buffer 2 or the next descriptor, depending on the value of TCH (TDES0[20]). †

Table 17-10: Transmit Descriptor 2 (TDES2)

Bit	Description
31:09	Buffer 1 Address Pointer These bits indicate the physical address of Buffer 1. There is no limitation on the buffer address alignment. †

Table 17-11: Transmit Descriptor 3 (TDES3)

Bit	Description
31:09	Buffer 2 Address Pointer (Next Descriptor Address) Indicates the physical address of Buffer 2 when a descriptor ring structure is used. If the Second Address Chained (TDES1[24]) bit is set, this address contains the pointer to the physical memory where the Next descriptor is present. The buffer address pointer must be aligned to the bus width only when TDES1[24] is set. (LSBs are ignored internally.) †

Table 17-12: Transmit Descriptor 6 (TDES6)

Bit	Description
31:09	TTSL: Transmit Frame Timestamp Low This field is updated by DMA with the least significant 32 bits of the timestamp captured for the corresponding transmit frame. This field has the timestamp only if the Last Segment bit (LS) in the descriptor is set and Timestamp status (TTSS) bit is set. †

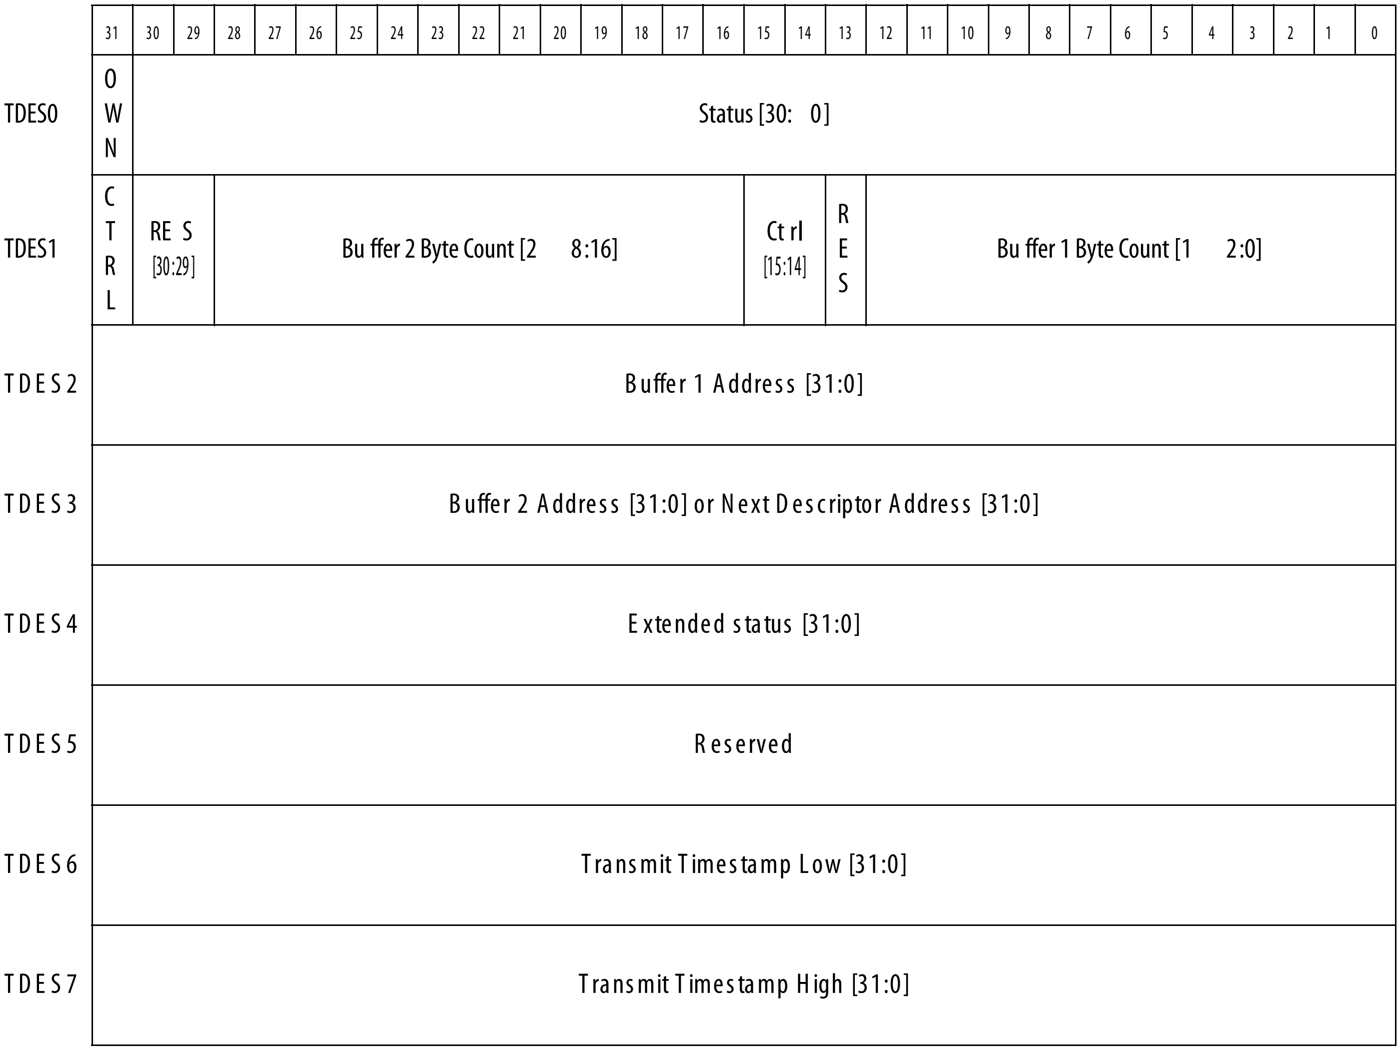
Table 17-13: Transmit Descriptor 7 (TDES7)

Bit	Description
31:09	TTSH: Transmit Frame Timestamp High This field is updated by DMA with the most significant 32 bits of the timestamp captured for the corresponding receive frame. This field has the timestamp only if the Last Segment bit (LS) in the descriptor is set and Timestamp status (TTSS) bit is set. †

Receive Descriptor

The receive descriptor can have 32 bytes of descriptor data (8 DWORDs) when advanced timestamp or IPC Full Offload feature is selected. When either of these features is enabled, the Software should set Bit 7 of Register 0 (Bus Mode Register) so that the DMA operates with extended descriptor size. When this control bit is reset, the RDES0[0] is always cleared and the RDES4-RDES7 descriptor space is not valid. †

Figure 17-13: Receive Descriptor Fields Format



Receive Descriptor Field 0 (RDES0)

Table 17-14: Receive Descriptor Field 0 (RDES0)

Bit	Description
31	OWN: Own Bit When set, this bit indicates that the descriptor is owned by the DMA of the EMAC. When this bit is reset, this bit indicates that the descriptor is owned by the Host. The DMA clears this bit either when it completes the frame reception or when the buffers that are associated with this descriptor are full.
30	AFM: Destination Address Filter Fail When set, this bit indicates a frame that failed in the DA Filter in the MAC. †
29:16	FL: Frame Length These bits indicate the byte length of the received frame that was transferred to host memory (including CRC). This field is valid when Last Descriptor (RDES0[8]) is set and either the Descriptor Error (RDES0[14]) or Overflow Error bits are reset. The frame length also includes the two bytes appended to the Ethernet frame when IP checksum calculation (Type 1) is enabled and the received frame is not a MAC control frame. This field is valid when Last Descriptor (RDES0[8]) is set. When the Last Descriptor and Error Summary bits are not set, this field indicates the accumulated number of bytes that have been transferred for the current frame. †
15	ES: Error Summary Indicates the logical OR of the following bits: • RDES0[1]: CRC Error • RDES0[3]: Receive Error • RDES0[4]: Watchdog Timeout • RDES0[6]: Late Collision • RDES0[7]: Giant Frame • RDES4[4:3]: IP Header or Payload Error (Receive Descriptor Field 4 (RDES4)) • RDES0[11]: Overflow Error • RDES0[14]: Descriptor Error This field is valid only when the Last Descriptor (RDES0[8]) is set. †
14	DE: Descriptor Error When set, this bit indicates a frame truncation caused by a frame that does not fit within the current descriptor buffers, and that the DMA does not own the Next descriptor. The frame is truncated. This field is valid only when the Last Descriptor (RDES0[8]) is set. †
13	SAF: Source Address Filter Fail When set, this bit indicates that the SA field of frame failed the SA Filter in the MAC. †

Bit	Description
12	LE: Length Error When set, this bit indicates that the actual length of the frame received and that the Length/ Type field does not match. This bit is valid only when the Frame Type (RDES0[5]) bit is reset. †
11	OE: Overflow Error When set, this bit indicates that the received frame was damaged because of buffer overflow in MTL. Note: This bit is set only when the DMA transfers a partial frame to the application. This happens only when the RX FIFO buffer is operating in the threshold mode. In the store-and-forward mode, all partial frames are dropped completely in RX FIFO buffer. †
10	VLAN: VLAN Tag When set, this bit indicates that the frame to which this descriptor is pointing is a VLAN frame tagged by the MAC. The VLAN tagging depends on checking the VLAN fields of received frame based on the Register 7 (VLAN Tag Register) setting. †
9	FS: First Descriptor When set, this bit indicates that this descriptor contains the first buffer of the frame. If the size of the first buffer is 0, the second buffer contains the beginning of the frame. If the size of the second buffer is also 0, the next descriptor contains the beginning of the frame. †
8	LS: Last Descriptor When set, this bit indicates that the buffers pointed to by this descriptor are the last buffers of the frame †
7	Timestamp Available, IP Checksum Error (Type1), or Giant Frame When advanced timestamp feature is present, when set, this bit indicates that a snapshot of the Timestamp is written in descriptor words 6 (RDES6) and 7 (RDES7). This is valid only when the Last Descriptor bit (RDES0[8]) is set. When IP Checksum Engine (Type 1) is selected, this bit, when set, indicates that the 16-bit IPv4 Header checksum calculated by the EMAC did not match the received checksum bytes. Otherwise, this bit, when set, indicates the Giant frame Status. Giant frames are larger than 1,518-byte (or 1,522-byte for VLAN or 2,000-byte when Bit 27 (2KPE) of MAC Configuration register is set) normal frames and larger than 9,018-byte (9,022-byte for VLAN) frame when Jumbo frame processing is enabled.
6	LC: Late Collision When set, this bit indicates that a late collision has occurred while receiving the frame in the half-duplex mode. †

Bit	Description
5	FT: Frame Type When set, this bit indicates that the receive frame is an Ethernet-type frame (the LT field is greater than or equal to 0x0600). When this bit is reset, it indicates that the received frame is an IEEE802.3 frame. This bit is not valid for Runt frames less than 14 bytes.
4	RWT: Receive Watchdog Timeout When set, this bit indicates that the receive Watchdog Timer has expired while receiving the current frame and the current frame is truncated after the Watchdog Timeout. †
3	RE: Receive Error When set, this bit indicates that the `gmii_rxer_i` signal is asserted while `gmii_rxdv_i` is asserted during frame reception.
2	DE: Dribble Bit Error When set, this bit indicates that the received frame has a non-integer multiple of bytes (odd nibbles). This bit is valid only in the MII Mode. †
1	CE: CRC Error When set, this bit indicates that a CRC error occurred on the received frame. This field is valid only when the Last Descriptor (RDES0[8]) is set. †
0	Extended Status Available/RX MAC Address When either advanced timestamp or IP Checksum Offload (Type 2) is present, this bit, when set, indicates that the extended status is available in descriptor word 4 (RDES4). This is valid only when the Last Descriptor bit (RDES0[8]) is set. When Advance Timestamp Feature or IPC Full Offload is not selected, this bit indicates RX MAC Address status. When set, this bit indicates that the RX MAC Address registers value (1 to 15) matched the frame's DA field. When reset, this bit indicates that the RX MAC Address Register 0 value matched the DA field. †

Related Information

Receive Descriptor Field 1 (RDES1)

Table 17-15: Receive Descriptor Field 1 (RDES1)

Bit	Description
31	DIC: Disable Interrupt on Completion When set, this bit prevents setting the Status Register's RI bit (CSR5[6]) for the received frame ending in the buffer indicated by this descriptor. This, in turn, disables the assertion of the interrupt to Host because of RI for that frame. †
30:29	Reserved †
28:16	RBS2: Receive Buffer 2 Size These bits indicate the second data buffer size, in bytes. The buffer size must be a multiple of 4, even if the value of RDES3 (buffer2 address pointer) in Receive Descriptor Field 3 (RDES3) is not aligned to bus width. If the buffer size is not an appropriate multiple of 4, the resulting behavior is undefined. This field is not valid if RDES1[14] is set. For more information about calculating buffer sizes, refer to `Buffer Size Calculations`.
15	RER: Receive End of Ring When set, this bit indicates that the descriptor list reached its final descriptor. The DMA returns to the base address of the list, creating a descriptor ring. †
14	RCH: Second Address Chained When set, this bit indicates that the second address in the descriptor is the Next descriptor address rather than the second buffer address. When this bit is set, RBS2 (RDES1[28:16]) is a "don't care" value. RDES1[15] takes precedence over RDES1[14]. †
13	Reserved †
12:0	RBS1: Receive Buffer 1 Size Indicates the first data buffer size in bytes. The buffer size must be a multiple of 4, even if the value of RDES2 (buffer1 address pointer), in Receive Descriptor Field 2 (RDES2), is not aligned. When the buffer size is not a multiple of 4, the resulting behavior is undefined. If this field is 0, the DMA ignores this buffer and uses Buffer 2 or next descriptor depending on the value of RCH (Bit 14). For more information about calculating buffer sizes, refer to `Buffer Size Calculations`.

Receive Descriptor Fields (RDES2) and (RDES3)

Receive Descriptor Field 2 (RDES2)

Table 17-16: Receive Descriptor Field 2 (RDES2)

Bit	Description
31:0	Buffer 1 Address Pointer These bits indicate the physical address of Buffer 1. There are no limitations on the buffer address alignment except for the following condition: The DMA uses the value programmed in RDES2[1:0] for its address generation when the RDES2 value is used to store the start of the frame. The DMA performs a write operation with the RDES2[1:0] bits as 0 during the transfer of the start of the frame but the frame is shifted as per the actual buffer address pointer. The DMA ignores RDES2[1:0] if the address pointer is to a buffer where the middle or last part of the frame is stored. For more information about buffer address alignment, refer to `Host Data Buffer Alignment`.

Receive Descriptor Field 3 (RDES3)

Table 17-17: Receive Descriptor Field 3 (RDES3)

Bit	Description
31:0	Buffer 2 Address Pointer (Next Descriptor Address) These bits indicate the physical address of Buffer 2 when a descriptor ring structure is used. If the Second Address Chained (RDES1[24]) bit, in Receive Descriptor Field 1 (RDES1), is set, this address contains the pointer to the physical memory where the Next descriptor is present. If RDES1[24], in Receive Descriptor Field 1 (RDES1), is set, the buffer (Next descriptor) address pointer must be bus width-aligned (RDES3[1:0] = 0. LSBs are ignored internally.) However, when RDES1[24], in Receive Descriptor Field 1 (RDES1), is reset, there are no limitations on the RDES3 value, except for the following condition: The DMA uses the value programmed in RDES3 [1:0] for its buffer address generation when the RDES3 value is used to store the start of frame. The DMA ignores RDES3 [1:0] if the address pointer is to a buffer where the middle or last part of the frame is stored.

Related Information

Receive Descriptor Field 1 (RDES1) on page 17-50

Receive Descriptor Field 4 (RDES4)

The extended status is written only when there is status related to IPC or timestamp available. The availability of extended status is indicated by Bit 0 in RDES0. This status is available only when the Advance Timestamp or IPC Full Offload feature is selected.

Table 17-18: Receive Descriptor Field 4 (RDES4)

Bit	Description
31:28	Reserved †
27:26	Layer 3 and Layer 4 Filter Number Matched These bits indicate the number of the Layer 3 and Layer 4 Filter that matched the received frame. • 00: Filter 0 • 01: Filter 1 • 10: Filter 2 • 11: Filter 3 This field is valid only when Bit 24 or Bit 25 is set high. When more than one filter matches, these bits give only the lowest filter number. †
25	Layer 4 Filter Match When set, this bit indicates that the received frame matches one of the enabled Layer 4 Port Number fields. This status is given only when one of the following conditions is true: • Layer 3 fields are not enabled and all enabled Layer 4 fields match. • All enabled Layer 3 and Layer 4 filter fields match. When more than one filter matches, this bit gives the layer 4 filter status of filter indicated by Bits [27:26]. †
24	Layer 3 Filter Match When set, this bit indicates that the received frame matches one of the enabled Layer 3 IP Address fields. This status is given only when one of the following conditions is true: • All enabled Layer 3 fields match and all enabled Layer 4 fields are bypassed. • All enabled filter fields match. When more than one filter matches, this bit gives the layer 3 filter status of filter indicated by Bits [27:26]. †
23:15	Reserved
14	Timestamp Dropped When set, this bit indicates that the timestamp was captured for this frame but got dropped in the MTL RX FIFO buffer because of overflow.
13	PTP Version When set, this bit indicates that the received PTP message is having the IEEE 1588 version 2 format. When reset, it has the version 1 format.

Bit	Description
12	PTP Frame Type When set, this bit indicates that the PTP message is sent directly over Ethernet. When this bit is not set and the message type is non-zero, it indicates that the PTP message is sent over UDP-IPv4 or UDP-IPv6. The information about IPv4 or IPv6 can be obtained from Bits 6 and 7.
11:8	Message Type These bits are encoded to give the type of the message received. • 0000: No PTP message received • 0001: SYNC (all clock types) • 0010: Follow_Up (all clock types) • 0011: Delay_Req (all clock types) • 0100: Delay_Resp (all clock types) • 0101: Pdelay_Req (in peer-to-peer transparent clock) • 0110: Pdelay_Resp (in peer-to-peer transparent clock) • 0111: Pdelay_Resp_Follow_Up (in peer-to-peer transparent clock) • 1000: Announce • 1001: Management • 1010: Signaling • 1011-1110: Reserved • 1111: PTP packet with Reserved message type
7	IPv6 Packet Received When set, this bit indicates that the received packet is an IPv6 packet. This bit is updated only when Bit 10 (IPC) of Register 0 (MAC Configuration Register) is set.
6	IPv4 Packet Received When set, this bit indicates that the received packet is an IPv4 packet. This bit is updated only when Bit 10 (IPC) of Register 0 (MAC Configuration Register) is set.
5	IP Checksum Bypassed When set, this bit indicates that the checksum offload engine is bypassed.
4	IP Payload Error When set, this bit indicates that the 16-bit IP payload checksum (that is, the TCP, UDP, or ICMP checksum) that the EMAC calculated does not match the corresponding checksum field in the received segment. It is also set when the TCP, UDP, or ICMP segment length does not match the payload length value in the IP Header field. This bit is valid when either Bit 7 or Bit 6 is set.

Bit	Description
3	IP Header Error When set, this bit indicates that either the 16-bit IPv4 header checksum calculated by the EMAC does not match the received checksum bytes, or the IP datagram version is not consistent with the Ethernet Type value. This bit is valid when either Bit 7 or Bit 6 is set.
2:0	IP Payload Type These bits indicate the type of payload encapsulated in the IP datagram processed by the receive Checksum Offload Engine (COE). The COE also sets these bits to 0 if it does not process the IP datagram's payload due to an IP header error or fragmented IP. • 0: Unknown or did not process IP payload • 1: UDP • 2: TCP • 3: ICMP • 4–7: Reserved This bit is valid when either Bit 7 or Bit 6 is set.

Receive Descriptor Fields (RDES6) and (RDES7)

Receive Descriptor Fields 6 (RDES6) and RDES7 contain the snapshot of the timestamp. The availability of the snapshot of the timestamp in RDES6 and RDES7 is indicated by Bit 7 in the RDES0 descriptor.

Related Information

Receive Descriptor Field 0 (RDES0) on page 17-47

Receive Descriptor Field 6 (RDES6)

Table 17-19: Receive Descriptor Field 6 (RDES6)

Bit	Description
31:0	RTSL: Receive Frame Timestamp Low This field is updated by DMA with the least significant 32 bits of the timestamp captured for the corresponding receive frame. This field is updated by DMA only for the last descriptor of the receive frame which is indicated by Last Descriptor status bit (RDES0[8]) in RDES0.

Related Information

Receive Descriptor Field 0 (RDES0) on page 17-47

Receive Descriptor Field 7 (RDES7)

Table 17-20: Receive Descriptor Field 7 (RDES7)

Bit	Description
31:0	RTSH: Receive Frame Timestamp High This field is updated by DMA with the most significant 32 bits of the timestamp captured for the corresponding receive frame. This field is updated by DMA only for the last descriptor of the receive frame which is indicated by Last Descriptor status bit (RDES0[8]) in RDES0.

Initializing DMA

This section provides the instructions for initializing the DMA/MAC registers in the proper sequence. Perform the following steps to initialize the DMA:

1. Provide a software reset. This resets all of the EMAC internal registers and logic. (DMA Register 0 (Bus Mode Register) – bit 0). †
2. Wait for the completion of the reset process (poll bit 0 of the DMA Register 0 (Bus Mode Register), which is only cleared after the reset operation is completed). †
3. Poll the bits of Register 11 (AHB or AXI Status) to confirm that all previously initiated (before software-reset) or ongoing transactions are complete.

   Note: If the application cannot poll the register after soft reset (because of performance reasons), then it is recommended that you continue with the next steps and check this register again (as mentioned in 12 on page 1-56) before triggering the DMA operations.†
4. Program the following fields to initialize the Bus Mode Register by setting values in DMA Register 0 (Bus Mode Register):†
   - Mixed Burst and AAL
   - Fixed burst or undefined burst†
   - Burst length values and burst mode values†
   - Descriptor Length (only valid if Ring Mode is used)†
   - TX and RX DMA Arbitration scheme†
5. Program the interface options in Register 10 (AXI Bus Mode Register). If fixed burst-length is enabled, then select the maximum burst-length possible on the bus (bits[7:1]).†
6. Create a proper descriptor chain for transmit and receive. In addition, ensure that the receive descriptors are owned by DMA (bit 31 of descriptor should be set). When OSF mode is used, at least two descriptors are required.
7. Make sure that your software creates three or more different transmit or receive descriptors in the chain before reusing any of the descriptors.†
8. Initialize receive and transmit descriptor list address with the base address of the transmit and receive descriptor (Register 3 (Receive Descriptor List Address Register) and Register 4 (Transmit Descriptor List Address Register) respectively).†
9. Program the following fields to initialize the mode of operation in Register 6 (Operation Mode Register):

- Receive and Transmit Store And Forward†
- Receive and Transmit Threshold Control (RTC and TTC)†
- Hardware Flow Control enable†
- Flow Control Activation and De-activation thresholds for MTL Receive and Transmit FIFO buffers (RFA and RFD)†
- Error frame and undersized good frame forwarding enable†
- OSF Mode†

10. Clear the interrupt requests, by writing to those bits of the status register (interrupt bits only) that are set. For example, by writing 1 into bit 16, the normal interrupt summary clears this bit (DMA Register 5 (Status Register)).†
11. Enable the interrupts by programming the Register 7 (Interrupt Enable Register).†

    Note: Perform 12 on page 1-56 only if you did not perform 3 on page 1-55.†
12. Read Register 11 (AHB or AXI Status) to confirm that all previous transactions are complete.†

    Note: If any previous transaction is still in progress when you read the Register 11 (AHB or AXI Status), then it is strongly recommended to check the slave components addressed by the master interface.†
13. Start the receive and transmit DMA by setting SR (bit 1) and ST (bit 13) of the control register (DMA Register 6 (Operation Mode Register). †

Detailed bit map of the descriptor structure

Initializing MAC

The following MAC Initialization operations can be performed after DMA initialization. If the MAC initialization is done before the DMA is set-up, then enable the MAC receiver (last step below) only after the DMA is active. Otherwise, received frames fill the RX FIFO buffer and overflow.

1. Program the EMAC Register 4 (GMII Address Register) for controlling the management cycles for external PHY. For example, Physical Layer Address PA (bits 15-11). In addition, set bit 0 (GMII Busy) for writing into PHY and reading from PHY. †
2. Read the 16-bit data of Register 5 (GMII Data Register) from the PHY for link up, speed of operation, and mode of operation, by specifying the appropriate address value in bits 15-11 of Register 4 (GMII Address Register). †
3. Provide the MAC address registers (Register 16 (MAC Address0 High Register) and Register 17 (MAC Address0 Low Register)). Because 128 MAC addresses are supported, you need to program the MAC addresses accordingly.
4. Program Register 2 (Hash Table High Register) and Register 3 (Hash Table Low Register).
5. Program the following fields to set the appropriate filters for the incoming frames in Register 1 (MAC Frame Filter): †

    - Receive All †
    - Promiscuous mode †
    - Hash or Perfect Filter †
    - Unicast, multicast, broadcast, and control frames filter settings †
6. Program the following fields for proper flow control in Register 6 (Flow Control Register): †

    - Pause time and other pause frame control bits †
    - Receive and Transmit Flow control bits †
    - Flow Control Busy/Backpressure Activate †

7. Program the Interrupt Mask register bits, as required, and if applicable, for your configuration. †
8. Program the appropriate fields in Register 0 (MAC Configuration Register). For example, Interframe gap while transmission and jabber disable. Based on the Auto-negotiation you can set the Duplex mode (bit 11) or port select (bit 15). †
9. Set Bit 3 (TE) and Bit 2 (RE) in Register 0 (MAC Configuration Register). †

Note: Do not change the configuration (such as duplex mode, speed, port, or loopback) when the EMAC DMA is actively transmitting or receiving. The Software should change these parameters only when the EMAC DMA transmitter and receiver are not active.

Performing Normal Receive and Transmit Operation

For normal operation, perform the following steps: †

1. For normal transmit and receive interrupts, read the interrupt status. Then, poll the descriptors, reading the status of the descriptor owned by the Host (either transmit or receive). †
2. Set appropriate values for the descriptors, ensuring that transmit and receive descriptors are owned by the DMA to resume the transmission and reception of data. †
3. If the descriptors are not owned by the DMA (or no descriptor is available), the DMA goes into SUSPEND state. The transmission or reception can be resumed by freeing the descriptors and issuing a poll demand by writing 0 into the TX/RX poll demand register (Register 1 (Transmit Poll Demand Register) and Register 2 (Receive Poll Demand Register). †
4. The values of the current host transmitter or receiver descriptor address pointer can be read for the debug process (Register 18 (Current Host Transmit Descriptor Register) and Register 19 (Current Host Receive Descriptor Register). †
5. The values of the current host transmit buffer address pointer and receive buffer address pointer can be read for the debug process (Register 20 (Current Host Transmit Buffer Address Register) and Register 21 (Current Host Receive Buffer Address Register). †

Stopping and Starting Transmission

Perform the following steps to pause the transmission for some time: †

1. Disable the transmit DMA (if applicable), by clearing bit 13 (Start or Stop Transmission Command) of Register 6 (Operation Mode Register). †
2. Wait for any previous frame transmissions to complete. You can check this by reading the appropriate bits of Register 9 (Debug Register). †
3. Disable the MAC transmitter and MAC receiver by clearing Bit 3 (TE) and Bit 2 (RE) in Register 0 (MAC Configuration Register). †
4. Disable the receive DMA (if applicable), after making sure that the data in the RX FIFO buffer is transferred to the system memory (by reading Register 9 (Debug Register). †
5. Make sure that both TX FIFO buffer and RX FIFO buffer are empty. †
6. To re-start the operation, first start the DMAs, and then enable the MAC transmitter and receiver. †

Programming Guidelines for Energy Efficient Ethernet

Entering and Exiting the TX LPI Mode

The Energy Efficient Ethernet (EEE) feature is available in the EMAC. To use it, perform the following steps during EMAC initialization:

1. Read the PHY register through the MDIO interface, check if the remote end has the EEE capability, and then negotiate the timer values. †
2. Program the PHY registers through the MDIO interface (including the RX_CLK_stoppable bit that indicates to the PHY whether to stop RX clock in LPI mode.) †
3. Program Bits[16:5], LST, and Bits[15:0], TWT, in Register 13 (LPI Timers Control Register). †
4. Read the link status of the PHY chip by using the MDIO interface and update Bit 17 (PLS) of Register 12 (LPI Control and Status Register) accordingly. This update should be done whenever the link status in the PHY chip changes. †
5. Set Bit 16 (LPIEN) of Register 12 (LPI Control and Status Register) to make the MAC enter the LPI state. The MAC enters the LPI mode after completing the transmission in progress and sets Bit 0 (TLPIEN). †

   Note: To make the MAC enter the LPI state only after it completes the transmission of all queued frames in the TX FIFO buffer, you should set Bit 19 (LPITXA) in Register 12 (LPI Control and Status Register). †

   Note: To switch off the transmit clock during the LPI state, use the `sbd_tx_clk_gating_ctrl_o` signal for gating the clock input. †

   Note: To switch off the CSR clock or power to the rest of the system during the LPI state, you should wait for the TLPIEN interrupt of Register 12 (LPI Control and Status Register) to be generated. Restore the clocks before performing the 6 on page 1-58 when you want to come out of the LPI state. †
6. Reset Bit 16 (LPIEN) of Register 12 (LPI Control and Status Register) to bring the MAC out of the LPI state. †

The MAC waits for the time programmed in Bits [15:0], TWT, before setting the TLPIEX interrupt status bit and resuming the transmission. †

Gating Off the CSR Clock in the LPI Mode

You can gate off the CSR clock to save the power when the MAC is in the Low-Power Idle (LPI) mode.†

Gating Off the CSR Clock in the RX LPI Mode

The following operations are performed when the MAC receives the LPI pattern from the PHY. †

1. The MAC RX enters the LPI mode and the RX LPI entry interrupt status [RLPIEN interrupt of Register 12 (`LPI_Control_Status`)] is set. †
2. The interrupt pin (`sbd_intr_o`) is asserted. The `sbd_intr_o` interrupt is cleared when the host reads the Register 12 (`LPI_Control_Status`). †

After the `sbd_intr_o` interrupt is asserted and the MAC TX is also in the LPI mode, you can gate-off the CSR clock. If the MAC TX is not in the LPI mode when you gate off the CSR clock, the events on the MAC transmitter do not get reported or updated in the CSR. †

For restoring the CSR clock, wait for the LPI exit indication from the PHY after which the MAC asserts the LPI exit interrupt on `lpi_intr_o` (synchronous to `clk_rx_i`). The `lpi_intr_o` interrupt is cleared when Register 12 is read. †

Gating Off the CSR Clock in the TX LPI Mode

The following operations are performed when Bit 16 (LPIEN) of Register 12 (LPI Control and Status Register) is set: †

1. The Transmit LPI Entry interrupt (TLPIEN bit of Register 12) is set. †
2. The interrupt pin (`sbd_intr_o`) is asserted. The `sbd_intr_o` interrupt is cleared when the host reads the Register 12. †

After the `sbd_intr_o` interrupt is asserted and the MAC RX is also in the LPI mode, you can gate off the CSR clock. If the MAC RX is not in the LPI mode when you gate off the CSR clock, the events on the MAC receiver do not get reported or updated in the CSR. †

For restoring the CSR clock, switch on the CSR clock when the MAC has to come out of the TX LPI mode. †

After the CSR clock is resumed, reset Bit 16 (LPIEN) of Register 12 (LPI Control and Status Register) to bring the MAC out of the LPI mode. †

Programming Guidelines for Flexible Pulse-Per-Second (PPS) Output

Generating Single Pulse on PPS

To generate single Pulse on PPS: †

1. Program 11 or 10 (for interrupt) in Bits [6:5], TRGTMODSEL, of Register 459 (PPS Control Register). This instructs the MAC to use the Target Time registers (register 455 and 456) for start time of PPS signal output. †
2. Program the start time value in the Target Time registers (register 455 and 456). †
3. Program the width of the PPS signal output in Register 473 (PPS0 Width Register). †
4. Program Bits [3:0], PPSCMD, of Register 459 (PPS Control Register) to 0001. This instructs the MAC to generate single pulse on the PPS signal output at the time programmed in the Target Time registers (register 455 and 456). †

Once the PPSCMD is executed (PPSCMD bits = 0), you can cancel the pulse generation by giving the Cancel Start Command (PPSCMD=0011) before the programmed start time elapses. You can also program the behavior of the next pulse in advance. To program the next pulse: †

1. Program the start time for the next pulse in the Target Time registers (register 455 and 456). This time should be more than the time at which the falling edge occurs for the previous pulse. †
2. Program the width of the next PPS signal output in Register 473 (PPS0 Width Register). †
3. Program Bits [3:0], PPSCMD, of Register 459 (PPS Control Register) to generate a single pulse after the time at which the previous pulse is de-asserted. This instructs the MAC to generate single pulse on the PPS signal output, at the time programmed in Target Time registers. If you give this command before the previous pulse becomes low, then the new command overwrites the previous command and the EMAC may generate only 1 extended pulse.

Generating a Pulse Train on PPS

To generate a pulse train on PPS: †

1. Program 11 or 10 (for interrupt) in Bits [6:5], TRGTMODSEL, of Register 459 (PPS Control Register). This instructs the MAC to use the Target Time registers (register 455 and 456) for start time of the PPS signal output. †
2. Program the start time value in the Target Time registers (register 455 and 456). †
3. Program the interval value between the train of pulses on the PPS signal output in Register 473 (PPS0 Width Register). †
4. Program the width of the PPS signal output in Register 473 (PPS0 Width Register). †
5. Program Bits[3:0], PPSCMD, of Register 459 (PPS Control Register) to 0010. This instructs the MAC to generate train of pulses on the PPS signal output with start time programmed in Target Time registers (register 455 and 456). By default, the PPS pulse train is free-running unless stopped by 'STOP Pulse train at time' or 'STOP Pulse Train immediately' commands. †
6. Program the stop value in the Target Time registers (register 455 and 456). Ensure that Bit 31 (TSTRBUSY) of Register 456 (Target Time Nanoseconds Register) is reset before programming the Target Time registers (register 455 and 456) again. †
7. Program the PPSCMD field (bit 3:0) of Register 459 (PPS Control Register) to 0100. This stops the train of pulses on PPS signal output after the programmed stop time specified in 6 on page 1-60 elapses. †

You can stop the pulse train at any time by programming 0101 in the PPSCMD field. Similarly, you can cancel the Stop Pulse train command (given in 7 on page 1-60) by programming 0110 in the PPSCMD field before the time (programmed in 6 on page 1-60) elapses. You can cancel the pulse train generation by programming 0011 in the PPSCMD field before the programmed start time (in 2 on page 1-60) elapses. †

Generating an Interrupt without Affecting the PPS

The Bits [6:5], TRGTMODSEL, of the Register 459 (PPS Control Register) enable you to program the Target Time registers (register 455 and 456) to do any one of the following: †

- Generate only interrupts. †
- Generate interrupts and the PPS start and stop time. †
- Generate only PPS start and stop time. †

To program the Target Time registers (register 455 and 456) to generate only interrupt event: †

1. Program 00 (for interrupt) in Bits [6:5], TRGTMODSEL, of Register 459 (PPS Control Register). This instructs the MAC to use the Target Time registers (register 455 and 456) for target time interrupt. †
2. Program a target time value in the Target Time registers (register 455 and 456). This instructs the MAC to generate an interrupt when the target time elapses. If Bits [6:5], TRGTMODSEL, are changed (for example, to control the PPS), then the interrupt generation is over-written with the new mode and new programmed Target Time register value.

Ethernet MAC Address Map and Register Definitions

The address map and register definitions for the HPS-FPGA bridges consist of the following regions:

- EMAC Module 0
- EMAC Module 1

GMAC Register Group Register Descriptions

GMAC Register Group

Offset: 0x0

MAC_Configuration on page 17-126
The MAC Configuration register establishes receive and transmit operating modes.

MAC_Frame_Filter on page 17-134
The MAC Frame Filter register contains the filter controls for receiving frames. Some of the controls from this register go to the address check block of the MAC, which performs the first level of address filtering. The second level of filtering is performed on the incoming frame, based on other controls such as Pass Bad Frames and Pass Control Frames.

GMII_Address on page 17-140
The GMII Address register controls the management cycles to the external PHY through the management interface.

GMII_Data on page 17-142
The GMII Data register stores Write data to be written to the PHY register located at the address specified in Register 4 (GMII Address Register). This register also stores the Read data from the PHY register located at the address specified by Register 4.

Flow_Control on page 17-143
The Flow Control register controls the generation and reception of the Control (Pause Command) frames by the MAC's Flow control block. A Write to a register with the Busy bit set to '1' triggers the Flow Control block to generate a Pause Control frame. The fields of the control frame are selected as specified in the 802.3x specification, and the Pause Time value from this register is used in the Pause Time field of the control frame. The Busy bit remains set until the control frame is transferred onto the cable. The Host must make sure that the Busy bit is cleared before writing to the register.

VLAN_Tag on page 17-146
The VLAN Tag register contains the IEEE 802.1Q VLAN Tag to identify the VLAN frames. The MAC compares the 13th and 14th bytes of the receiving frame (Length/Type) with 16'h8100, and the following two bytes are compared with the VLAN tag. If a match occurs, the MAC sets the received VLAN bit in the receive frame status. The legal length of the frame is increased from 1,518 bytes to 1,522 bytes. Because the VLAN Tag register is double-synchronized to the (G)MII clock domain, then consecutive writes to these register should be performed only after at least four clock cycles in the destination clock domain.

Version on page 17-148
The Version registers identifies the version of the EMAC. This register contains two bytes: one specified by Synopsys to identify the core release number, and the other specified by Altera.

Debug on page 17-148
The Debug register gives the status of all main blocks of the transmit and receive data-paths and the FIFOs. An all-zero status indicates that the MAC is in idle state (and FIFOs are empty) and no activity is going on in the data-paths.

LPI_Control_Status on page 17-152
The LPI Control and Status Register controls the LPI functions and provides the LPI interrupt status. The status bits are cleared when this register is read.

LPI_Timers_Control on page 17-155
The LPI Timers Control register controls the timeout values in the LPI states. It specifies the time for which the MAC transmits the LPI pattern and also the time for which the MAC waits before resuming the normal transmission.

Interrupt_Status on page 17-156
The Interrupt Status register identifies the events in the MAC that can generate interrupt. All interrupt events are generated only when the corresponding optional feature is enabled.

Interrupt_Mask on page 17-159
The Interrupt Mask Register bits enable you to mask the interrupt signal because of the corresponding event in the Interrupt Status Register. The interrupt signal is sbd_intr_o.

MAC_Address0_High on page 17-160
The MAC Address0 High register holds the upper 16 bits of the first 6-byte MAC address of the station. The first DA byte that is received on the (G)MII interface corresponds to the LS byte (Bits [7:0]) of the MAC Address Low register. For example, if 0x112233445566 is received (0x11 in lane 0 of the first column) on the (G)MII as the destination address, then the MacAddress0 Register [47:0] is compared with 0x665544332211. Because the MAC address registers are double-synchronized to the (G)MII clock domains, then the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address0 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain.

MAC_Address0_Low on page 17-161
The MAC Address0 Low register holds the lower 32 bits of the first 6-byte MAC address of the station.

MAC_Address1_High on page 17-162
The MAC Address1 High register holds the upper 16 bits of the 2nd 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address1 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address1_Low on page 17-165
The MAC Address1 Low register holds the lower 32 bits of the 2nd 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address2_High on page 17-166
The MAC Address2 High register holds the upper 16 bits of the 3rd 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address2 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address2_Low on page 17-169
The MAC Address2 Low register holds the lower 32 bits of the 3rd 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address3_High on page 17-170
The MAC Address3 High register holds the upper 16 bits of the 4th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address3 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address3_Low on page 17-173
The MAC Address3 Low register holds the lower 32 bits of the 4th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address4_High on page 17-174
The MAC Address4 High register holds the upper 16 bits of the 5th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address4 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address4_Low on page 17-177
The MAC Address4 Low register holds the lower 32 bits of the 5th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address5_High on page 17-178
The MAC Address5 High register holds the upper 16 bits of the 6th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address5 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address5_Low on page 17-181
The MAC Address5 Low register holds the lower 32 bits of the 6th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address6_High on page 17-182
The MAC Address6 High register holds the upper 16 bits of the 7th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address6 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address6_Low on page 17-185
The MAC Address6 Low register holds the lower 32 bits of the 7th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address7_High on page 17-186
The MAC Address7 High register holds the upper 16 bits of the 8th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address7 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address7_Low on page 17-189
The MAC Address7 Low register holds the lower 32 bits of the 8th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address8_High on page 17-190
The MAC Address8 High register holds the upper 16 bits of the 9th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address8 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address8_Low on page 17-193
The MAC Address8 Low register holds the lower 32 bits of the 9th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address9_High on page 17-194
The MAC Address9 High register holds the upper 16 bits of the 10th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address9 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address9_Low on page 17-197
The MAC Address9 Low register holds the lower 32 bits of the 10th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address10_High on page 17-198
The MAC Address10 High register holds the upper 16 bits of the 11th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address10 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address10_Low on page 17-201
The MAC Address10 Low register holds the lower 32 bits of the 11th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address11_High on page 17-202
The MAC Address11 High register holds the upper 16 bits of the 12th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address11 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address11_Low on page 17-205
The MAC Address11 Low register holds the lower 32 bits of the 12th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address12_High on page 17-206
The MAC Address12 High register holds the upper 16 bits of the 13th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address12 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address12_Low on page 17-209
The MAC Address12 Low register holds the lower 32 bits of the 13th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address13_High on page 17-210
The MAC Address13 High register holds the upper 16 bits of the 14th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address13 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address13_Low on page 17-213
The MAC Address13 Low register holds the lower 32 bits of the 14th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address14_High on page 17-214
The MAC Address14 High register holds the upper 16 bits of the 15th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address14 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address14_Low on page 17-217
The MAC Address14 Low register holds the lower 32 bits of the 15th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address15_High on page 17-218
The MAC Address15 High register holds the upper 16 bits of the 16th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address15 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address15_Low on page 17-221
The MAC Address15 Low register holds the lower 32 bits of the 16th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

SGMII_RGMII_SMII_Control_Status on page 17-222
The SGMII/RGMII/SMII Status register indicates the status signals received by the RGMII interface (selected at reset) from the PHY.

MMC_Control on page 17-223
The MMC Control register establishes the operating mode of the management counters. Note: The bit 0 (Counters Reset) has higher priority than bit 4 (Counter Preset). Therefore, when the Software tries to set both bits in the same write cycle, all counters are cleared and the bit 4 is not set.

MMC_Receive_Interrupt on page 17-225
The MMC Receive Interrupt register maintains the interrupts that are generated when the following happens: * Receive statistic counters reach half of their maximum values (0x8000_0000 for 32-bit counter and 0x8000 for 16-bit counter). * Receive statistic counters cross their maximum values (0xFFFF_FFFF for 32-bit counter and 0xFFFF for 16-bit counter). When the Counter Stop Rollover is set, then interrupts are set but the counter remains at all-ones. The MMC Receive Interrupt register is a 32-bit wide register. An interrupt bit is cleared when the respective MMC counter that caused the interrupt is read. The least significant byte lane (Bits[7:0]) of the respective counter must be read in order to clear the interrupt bit.

MMC_Transmit_Interrupt on page 17-231
The MMC Transmit Interrupt register maintains the interrupts generated when transmit statistic counters reach half of their maximum values (0x8000_0000 for 32-bit counter and 0x8000 for 16-bit counter), and the maximum values (0xFFFF_FFFF for 32-bit counter and 0xFFFF for 16-bit counter). When Counter Stop Rollover is set, then interrupts are set but the counter remains at all-ones. The MMC Transmit Interrupt register is a 32-bit wide register. An interrupt bit is cleared when the respective MMC counter that caused the interrupt is read. The least significant byte lane (Bits[7:0]) of the respective counter must be read in order to clear the interrupt bit.

MMC_Receive_Interrupt_Mask on page 17-236
The MMC Receive Interrupt Mask register maintains the masks for the interrupts generated when the receive statistic counters reach half of their maximum value, or maximum value. This register is 32-bits wide.

MMC_Transmit_Interrupt_Mask on page 17-242
The MMC Transmit Interrupt Mask register maintains the masks for the interrupts generated when the transmit statistic counters reach half of their maximum value or maximum value. This register is 32-bits wide.

txoctetcount_gb on page 17-248
Number of bytes transmitted, exclusive of preamble and retried bytes, in good and bad frames

txframecount_gb on page 17-249
Number of good and bad frames transmitted, exclusive of retried frames

txbroadcastframes_g on page 17-249
Number of good broadcast frames transmitted

txmulticastframes_g on page 17-250
Number of good multicast frames transmitted

tx64octets_gb on page 17-250
Number of good and bad frames transmitted with length 64 bytes, exclusive of preamble and retried frames

tx65to127octets_gb on page 17-251
Number of good and bad frames transmitted with length between 65 and 127 (inclusive) bytes, exclusive of preamble and retried frames

tx128to255octets_gb on page 17-251
Number of good and bad frames transmitted with length between 128 and 255 (inclusive) bytes, exclusive of preamble and retried frames

tx256to511octets_gb on page 17-252
Number of good and bad frames transmitted with length between 256 and 511 (inclusive) bytes, exclusive of preamble and retried frames

tx512to1023octets_gb on page 17-253
Number of good and bad frames transmitted with length between 512 and 1,023 (inclusive) bytes, exclusive of preamble and retried frames

tx1024tomaxoctets_gb on page 17-253
Number of good and bad frames transmitted with length between 1,024 and maxsize (inclusive) bytes, exclusive of preamble and retried frames

txunicastframes_gb on page 17-254
Number of good and bad unicast frames transmitted

txmulticastframes_gb on page 17-254
Number of good and bad multicast frames transmitted

txbroadcastframes_gb on page 17-255
Number of good and bad broadcast frames transmitted

txunderflowerror on page 17-255
Number of frames aborted due to frame underflow error

txsinglecol_g on page 17-256
Number of successfully transmitted frames after a single collision in Half-duplex mode

txmulticol_g on page 17-256
Number of successfully transmitted frames after more than a single collision in Half-duplex mode

txdeferred on page 17-257
Number of successfully transmitted frames after a deferral in Halfduplex mode

txlatecol on page 17-257
Number of frames aborted due to late collision error

txexesscol on page 17-258
Number of frames aborted due to excessive (16) collision errors

txcarriererr on page 17-258
Number of frames aborted due to carrier sense error (no carrier or loss of carrier)

txoctetcnt on page 17-259
Number of bytes transmitted, exclusive of preamble, in good frames only

txframecount_g on page 17-260
Number of good frames transmitted

txexcessdef on page 17-260
Number of frames aborted due to excessive deferral error (deferred for more than two max-sized frame times)

txpauseframes on page 17-261
Number of good PAUSE frames transmitted

txvlanframes_g on page 17-261
Number of good VLAN frames transmitted, exclusive of retried frames

txoversize_g on page 17-262
Number of good and bad frames received

rxframecount_gb on page 17-262
Number of good and bad frames received

rxoctetcount_gb on page 17-263
Number of bytes received, exclusive of preamble, in good and bad frames

rxoctetcount_g on page 17-263
Number of bytes received, exclusive of preamble, only in good frames

rxbroadcastframes_g on page 17-264
Number of good broadcast frames received

rxmulticastframes_g on page 17-264
Number of good multicast frames received

rxcrcerror on page 17-265
Number of frames received with CRC error

rxalignmenterror on page 17-265
Number of frames received with alignment (dribble) error. Valid only in 10/100 mode

rxrunterror on page 17-266
Number of frames received with runt (<64 bytes and CRC error) error

rxjabbererror on page 17-266
Number of giant frames received with length (including CRC) greater than 1,518 bytes (1,522 bytes for VLAN tagged) and with CRC error. If Jumbo Frame mode is enabled, then frames of length greater than 9,018 bytes (9,022 for VLAN tagged) are considered as giant frames

rxundersize_g on page 17-267
Number of frames received with length less than 64 bytes, without any errors

rxoversize_g on page 17-268
Number of frames received with length greater than the maxsize (1,518 or 1,522 for VLAN tagged frames), without errors

rx64octets_gb on page 17-268
Number of good and bad frames received with length 64 bytes, exclusive of preamble

rx65to127octets_gb on page 17-269
Number of good and bad frames received with length between 65 and 127 (inclusive) bytes, exclusive of preamble

rx128to255octets_gb on page 17-269
Number of good and bad frames received with length between 128 and 255 (inclusive) bytes, exclusive of preamble

rx256to511octets_gb on page 17-270
Number of good and bad frames received with length between 256 and 511 (inclusive) bytes, exclusive of preamble

rx512to1023octets_gb on page 17-270
Number of good and bad frames received with length between 512 and 1,023 (inclusive) bytes, exclusive of preamble

rx1024tomaxoctets_gb on page 17-271
Number of good and bad frames received with length between 1,024 and maxsize (inclusive) bytes, exclusive of preamble and retried frames

rxunicastframes_g on page 17-272
Number of good unicast frames received

rxlengtherror on page 17-272
Number of frames received with length error (length type field not equal to frame size), for all frames with valid length field

rxoutofrangetype on page 17-273
Number of frames received with length field not equal to the valid frame size (greater than 1,500 but less than 1,536)

rxpauseframes on page 17-273
Number of good and valid PAUSE frames received

rxfifooverflow on page 17-274
Number of missed received frames due to FIFO overflow

rxvlanframes_gb on page 17-274
Number of good and bad VLAN frames received

rxwatchdogerror on page 17-275
Number of frames received with error due to watchdog timeout error (frames with a data load larger than 2,048 bytes)

rxrcverror on page 17-275
Number of frames received with Receive error or Frame Extension error on the GMII or MII interface.

rxctrlframes_g on page 17-276
Number of received good control frames.

MMC_IPC_Receive_Interrupt_Mask on page 17-276
This register maintains the mask for the interrupt generated from the receive IPC statistic counters.

MMC_IPC_Receive_Interrupt on page 17-283
This register maintains the interrupts generated when receive IPC statistic counters reach half their maximum values (0x8000_0000 for 32-bit counter and 0x8000 for 16-bit counter), and when they cross their maximum values (0xFFFF_FFFF for 32-bit counter and 0xFFFF for 16-bit counter). When Counter Stop Rollover is set, then interrupts are set but the counter remains at all-ones. The MMC Receive Checksum Offload Interrupt register is 32-bits wide. When the MMC IPC counter that caused the interrupt is read, its corresponding interrupt bit is cleared. The counter's least-significant byte lane (bits[7:0]) must be read to clear the interrupt bit.

rxipv4_gd_frms on page 17-289
Number of good IPv4 datagrams received with the TCP, UDP, or ICMP payload

rxipv4_hdrerr_frms on page 17-290
Number of IPv4 datagrams received with header (checksum, length, or version mismatch) errors

rxipv4_nopay_frms on page 17-290
Number of IPv4 datagram frames received that did not have a TCP, UDP, or ICMP payload processed by the Checksum engine

rxipv4_frag_frms on page 17-291
Number of good IPv4 datagrams with fragmentation

rxipv4_udsbl_frms on page 17-291
Number of good IPv4 datagrams received that had a UDP payload with checksum disabled

rxipv6_gd_frms on page 17-292
Number of good IPv6 datagrams received with TCP, UDP, or ICMP payloads

rxipv6_hdrerr_frms on page 17-292
Number of IPv6 datagrams received with header errors (length or version mismatch)

rxipv6_nopay_frms on page 17-293
Number of IPv6 datagram frames received that did not have a TCP, UDP, or ICMP payload. This includes all IPv6 datagrams with fragmentation or security extension headers

rxudp_gd_frms on page 17-293
Number of good IP datagrams with a good UDP payload. This counter is not updated when the counter is incremented

rxudp_err_frms on page 17-294
Number of good IP datagrams whose UDP payload has a checksum error

rxtcp_gd_frms on page 17-295
Number of good IP datagrams with a good TCP payload

rxtcp_err_frms on page 17-295
Number of good IP datagrams whose TCP payload has a checksum error

rxicmp_gd_frms on page 17-296
Number of good IP datagrams with a good ICMP payload

rxicmp_err_frms on page 17-296
Number of good IP datagrams whose ICMP payload has a checksum error

rxipv4_gd_octets on page 17-297
Number of bytes received in good IPv4 datagrams encapsulating TCP, UDP, or ICMP data

rxipv4_hdrerr_octets on page 17-297
Number of bytes received in IPv4 datagrams with header errors (checksum, length, version mismatch). The value in the Length field of IPv4 header is used to update this counter

rxipv4_nopay_octets on page 17-298
Number of bytes received in IPv4 datagrams that did not have a TCP, UDP, or ICMP payload. The value in the IPv4 headers Length field is used to update this counter

rxipv4_frag_octets on page 17-299
Number of bytes received in fragmented IPv4 datagrams. The value in the IPv4 headers Length field is used to update this counter

rxipv4_udsbl_octets on page 17-299
Number of bytes received in a UDP segment that had the UDP checksum disabled. This counter does not count IP Header bytes

rxipv6_gd_octets on page 17-300
Number of bytes received in good IPv6 datagrams encapsulating TCP, UDP or ICMPv6 data

rxipv6_hdrerr_octets on page 17-300
Number of bytes received in IPv6 datagrams with header errors (length, version mismatch). The value in the IPv6 headers Length field is used to update this counter

rxipv6_nopay_octets on page 17-301
Number of bytes received in IPv6 datagrams that did not have a TCP, UDP, or ICMP payload. The value in the IPv6 headers Length field is used to update this counter

rxudp_gd_octets on page 17-301
Number of bytes received in a good UDP segment. This counter does not count IP header bytes

rxudp_err_octets on page 17-302
Number of bytes received in a UDP segment that had checksum errors

rxtcp_gd_octets on page 17-303
Number of bytes received in a good TCP segment

rxtcperroctets on page 17-303
Number of bytes received in a TCP segment with checksum errors

rxicmp_gd_octets on page 17-304
Number of bytes received in a good ICMP segment

rxicmp_err_octets on page 17-304
Number of bytes received in an ICMP segment with checksum errors

L3_L4_Control0 on page 17-305
This register controls the operations of the filter 0 of Layer 3 and Layer 4.

Layer4_Address0 on page 17-307
Because the Layer 3 and Layer 4 Address Registers are double-synchronized to the Rx clock domains, then the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the Layer 3 and Layer 4 Address Registers are written. For proper synchronization updates, you should perform the consecutive writes to the same Layer 3 and Layer 4 Address Registers after at least four clock cycles delay of the destination clock.

Layer3_Addr0_Reg0 on page 17-308
For IPv4 frames, the Layer 3 Address 0 Register 0 contains the 32-bit IP Source Address field. For IPv6 frames, it contains Bits[31:0] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr1_Reg0 on page 17-309
For IPv4 frames, the Layer 3 Address 1 Register 0 contains the 32-bit IP Destination Address field. For IPv6 frames, it contains Bits[63:32] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr2_Reg0 on page 17-310
For IPv4 frames, the Layer 3 Address 2 Register 0 is reserved. For IPv6 frames, it contains Bits [95:64] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr3_Reg0 on page 17-311
For IPv4 frames, the Layer 3 Address 3 Register 0 is reserved. For IPv6 frames, it contains Bits [127:96] of the 128-bit IP Source Address or Destination Address field.

L3_L4_Control1 on page 17-312
This register controls the operations of the filter 0 of Layer 3 and Layer 4.

Layer4_Address1 on page 17-314
Because the Layer 3 and Layer 4 Address Registers are double-synchronized to the Rx clock domains, then the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the Layer 3 and Layer 4 Address Registers are written. For proper synchronization updates, you should perform the consecutive writes to the same Layer 3 and Layer 4 Address Registers after at least four clock cycles delay of the destination clock.

Layer3_Addr0_Reg1 on page 17-315
For IPv4 frames, the Layer 3 Address 0 Register 1 contains the 32-bit IP Source Address field. For IPv6 frames, it contains Bits[31:0] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr1_Reg1 on page 17-316
For IPv4 frames, the Layer 3 Address 1 Register 1 contains the 32-bit IP Destination Address field. For IPv6 frames, it contains Bits[63:32] of the 128-bit IP Source Address or Destination Address field

Layer3_Addr2_Reg1 on page 17-317
For IPv4 frames, the Layer 3 Address 2 Register 1 is reserved. For IPv6 frames, it contains Bits [95:64] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr3_Reg1 on page 17-318
For IPv4 frames, the Layer 3 Address 3 Register 1 is reserved. For IPv6 frames, it contains Bits [127:96] of the 128-bit IP Source Address or Destination Address field.

L3_L4_Control2 on page 17-318
This register controls the operations of the filter 2 of Layer 3 and Layer 4.

Layer4_Address2 on page 17-321
Because the Layer 3 and Layer 4 Address Registers are double-synchronized to the Rx clock domains, then the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the Layer 3 and Layer 4 Address Registers are written. For proper synchronization updates, you should perform the consecutive writes to the same Layer 3 and Layer 4 Address Registers after at least four clock cycles delay of the destination clock.

Layer3_Addr0_Reg2 on page 17-322
For IPv4 frames, the Layer 3 Address 0 Register 2 contains the 32-bit IP Source Address field. For IPv6 frames, it contains Bits [31:0] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr1_Reg2 on page 17-323
For IPv4 frames, the Layer 3 Address 1 Register 2 contains the 32-bit IP Destination Address field. For IPv6 frames, it contains Bits [63:32] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr2_Reg2 on page 17-324
For IPv4 frames, the Layer 3 Address 2 Register 2 is reserved. For IPv6 frames, it contains Bits [95:64] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr3_Reg2 on page 17-325
For IPv4 frames, the Layer 3 Address 3 Register 2 is reserved. For IPv6 frames, it contains Bits [127:96] of the 128-bit IP Source Address or Destination Address field.

L3_L4_Control3 on page 17-326
This register controls the operations of the filter 0 of Layer 3 and Layer 4.

Layer4_Address3 on page 17-328
Because the Layer 3 and Layer 4 Address Registers are double-synchronized to the Rx clock domains, then the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the Layer 3 and Layer 4 Address Registers are written. For proper synchronization updates, you should perform the consecutive writes to the same Layer 3 and Layer 4 Address Registers after at least four clock cycles delay of the destination clock.

Layer3_Addr0_Reg3 on page 17-329
For IPv4 frames, the Layer 3 Address 0 Register 3 contains the 32-bit IP Source Address field. For IPv6 frames, it contains Bits [31:0] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr1_Reg3 on page 17-330
For IPv4 frames, the Layer 3 Address 1 Register 3 contains the 32-bit IP Destination Address field. For IPv6 frames, it contains Bits [63:32] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr2_Reg3 on page 17-331
For IPv4 frames, the Layer 3 Address 2 Register 3 is reserved. For IPv6 frames, it contains Bits [95:64] of the 128-bit IP Source Address or Destination Address field.

Layer3_Addr3_Reg3 on page 17-332
For IPv4 frames, the Layer 3 Address 3 Register 3 is reserved. For IPv6 frames, it contains Bits [127:96] of the 128-bit IP Source Address or Destination Address field.

Hash_Table_Reg0 on page 17-333
This register contains the first 32 bits of the hash table. The 256-bit Hash table is used for group address filtering. For hash filtering, the content of the destination address in the incoming frame is passed through the CRC logic and the upper eight bits of the CRC register are used to index the content of the Hash table. The most significant bits determines the register to be used (Hash Table Register X), and the least significant five bits determine the bit within the register. For example, a hash value of 8b'10111111 selects Bit 31 of the Hash Table Register 5. The hash value of the destination address is calculated in the following way: 1. Calculate the 32-bit CRC for the DA (See IEEE 802.3, Section 3.2.8 for the steps to calculate CRC32). 2. Perform bitwise reversal for the value obtained in Step 1. 3. Take the upper 8 bits from the value obtained in Step 2. If the corresponding bit value of the register is 1'b1, the frame is accepted. Otherwise, it is rejected. If the Bit 1 (Pass All Multicast) is set in Register 1 (MAC Frame Filter), then all multicast frames are accepted regardless of the multicast hash values. Because the Hash Table register is double-synchronized to the (G)MII clock domain, the synchronization is triggered only when Bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the Hash Table Register X registers are written. Note: Because of double-synchronization, consecutive writes to this register should be performed after at least four clock cycles in the destination clock domain.

Hash_Table_Reg1 on page 17-333
This register contains the second 32 bits of the hash table.

Hash_Table_Reg2 on page 17-334
This register contains the third 32 bits of the hash table.

Hash_Table_Reg3 on page 17-334
This register contains the fourth 32 bits of the hash table.

Hash_Table_Reg4 on page 17-335
This register contains the fifth 32 bits of the hash table.

Hash_Table_Reg5 on page 17-335
This register contains the sixth 32 bits of the hash table.

Hash_Table_Reg6 on page 17-336
This register contains the seventh 32 bits of the hash table.

Hash_Table_Reg7 on page 17-336
This register contains the eighth 32 bits of the hash table.

VLAN_Incl_Reg on page 17-337
The VLAN Tag Inclusion or Replacement register contains the VLAN tag for insertion or replacement in the transmit frames.

VLAN_Hash_Table_Reg on page 17-338
The 16-bit Hash table is used for group address filtering based on VLAN tag when Bit 18 (VTHM) of Register 7 (VLAN Tag Register) is set. For hash filtering, the content of the 16-bit VLAN tag or 12-bit VLAN ID (based on Bit 16 (ETV) of VLAN Tag Register) in the incoming frame is passed through the CRC logic and the upper four bits of the calculated CRC are used to index the contents of the VLAN Hash table. For example, a hash value of 4b'1000 selects Bit 8 of the VLAN Hash table. The hash value of the destination address is calculated in the following way: 1. Calculate the 32-bit CRC for the VLAN tag or ID (See IEEE 802.3, Section 3.2.8 for the steps to calculate CRC32). 2. Perform bitwise reversal for the value obtained in Step 1. 3. Take the upper four bits from the value obtained in Step 2. If the corresponding bit value of the register is 1'b1, the frame is accepted. Otherwise, it is rejected. Because the Hash Table register is double-synchronized to the (G)MII clock domain, the synchronization is triggered only when Bits[15:8] (in little-endian mode) or Bits[7:0] (in big-endian mode) of this register are written. Notes: * Because of double-synchronization, consecutive writes to this register should be performed after at least four clock cycles in the destination clock domain.

Timestamp_Control on page 17-339
This register controls the operation of the System Time generator and the processing of PTP packets for timestamping in the Receiver.

Sub_Second_Increment on page 17-344
In the Coarse Update mode (TSCFUPDT bit in Register 448), the value in this register is added to the system time every clock cycle of clk_ptp_ref_i. In the Fine Update mode, the value in this register is added to the system time whenever the Accumulator gets an overflow.

System_Time_Seconds on page 17-345
The System Time -Seconds register, along with System-TimeNanoseconds register, indicates the current value of the system time maintained by the MAC. Though it is updated on a continuous basis, there is some delay from the actual time because of clock domain transfer latencies (from clk_ptp_ref_i to l3_sp_clk).

System_Time_Nanoseconds on page 17-346
The value in this field has the sub second representation of time, with an accuracy of 0.46 ns. When TSCTRLSSR is set, each bit represents 1 ns and the maximum value is 0x3B9A_C9FF, after which it rolls-over to zero.

System_Time_Seconds_Update on page 17-346
The System Time - Seconds Update register, along with the System Time - Nanoseconds Update register, initializes or updates the system time maintained by the MAC. You must write both of these registers before setting the TSINIT or TSUPDT bits in the Timestamp Control register.

System_Time_Nanoseconds_Update on page 17-347
Update system time

Timestamp_Addend on page 17-348
This register value is used only when the system time is configured for Fine Update mode (TSCFUPDT bit in Register 448). This register content is added to a 32-bit accumulator in every clock cycle (of clk_ptp_ref_i) and the system time is updated whenever the accumulator overflows.

Target_Time_Seconds on page 17-349
The Target Time Seconds register, along with Target Time Nanoseconds register, is used to schedule an interrupt event (Register 458[1] when Advanced Timestamping is enabled; otherwise, TS interrupt bit in Register14[9]) when the system time exceeds the value programmed in these registers.

Target_Time_Nanoseconds on page 17-349
Target time

System_Time_Higher_Word_Seconds on page 17-350
System time higher word

Timestamp_Status on page 17-351
Timestamp status. All bits except Bits[27:25] get cleared when the host reads this register.

PPS_Control on page 17-353
Controls timestamp Pulse-Per-Second output

Auxiliary_Timestamp_Nanoseconds on page 17-356
This register, along with Register 461 (Auxiliary Timestamp Seconds Register), gives the 64-bit timestamp stored as auxiliary snapshot. The two registers together form the read port of a 64-bit wide FIFO with a depth of 16. Multiple snapshots can be stored in this FIFO. The ATSNS bits in the Timestamp Status register indicate the fill-level of this FIFO. The top of the FIFO is removed only when the last byte of Register 461 (Auxiliary Timestamp - Seconds Register) is read. In the little-endian mode, this means when Bits[31:24] are read. In big-endian mode, it corresponds to the reading of Bits[7:0] of Register 461 (Auxiliary Timestamp - Seconds Register).

Auxiliary_Timestamp_Seconds on page 17-356
Contains the higher 32 bits (Seconds field) of the auxiliary timestamp.

PPS0_Interval on page 17-357
The PPS0 Interval register contains the number of units of sub-second increment value between the rising edges of PPS0 signal output (ptp_pps_o[0]).

PPS0_Width on page 17-358
The PPS0 Width register contains the number of units of sub-second increment value between the rising and corresponding falling edges of the PPS0 signal output (ptp_pps_o[0]).

MAC_Address16_High on page 17-358
The MAC Address16 High register holds the upper 16 bits of the 17th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address16 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address16_Low on page 17-362
The MAC Address16 Low register holds the lower 32 bits of the 17th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address17_High on page 17-362
The MAC Address17 High register holds the upper 16 bits of the 18th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address17 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address17_Low on page 17-365
The MAC Address17 Low register holds the lower 32 bits of the 18th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address18_High on page 17-366
The MAC Address18 High register holds the upper 16 bits of the 19th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address18 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address18_Low on page 17-369
The MAC Address18 Low register holds the lower 32 bits of the 19th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address19_High on page 17-370
The MAC Address19 High register holds the upper 16 bits of the 20th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address19 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address19_Low on page 17-373
The MAC Address19 Low register holds the lower 32 bits of the 20th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address20_High on page 17-374
The MAC Address20 High register holds the upper 16 bits of the 21th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address20 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address20_Low on page 17-377
The MAC Address20 Low register holds the lower 32 bits of the 21th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address21_High on page 17-378
The MAC Address21 High register holds the upper 16 bits of the 22th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address21 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address21_Low on page 17-381
The MAC Address21 Low register holds the lower 32 bits of the 22th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address22_High on page 17-382
The MAC Address22 High register holds the upper 16 bits of the 23th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address22 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address22_Low on page 17-385
The MAC Address22 Low register holds the lower 32 bits of the 23th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address23_High on page 17-386
The MAC Address23 High register holds the upper 16 bits of the 24th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address23 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address23_Low on page 17-389
The MAC Address23 Low register holds the lower 32 bits of the 24th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address24_High on page 17-390
The MAC Address24 High register holds the upper 16 bits of the 25th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address24 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address24_Low on page 17-393
The MAC Address24 Low register holds the lower 32 bits of the 25th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address25_High on page 17-394
The MAC Address25 High register holds the upper 16 bits of the 26th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address25 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address25_Low on page 17-397
The MAC Address25 Low register holds the lower 32 bits of the 26th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address26_High on page 17-398
The MAC Address26 High register holds the upper 16 bits of the 27th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address26 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address26_Low on page 17-401
The MAC Address26 Low register holds the lower 32 bits of the 27th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address27_High on page 17-402
The MAC Address27 High register holds the upper 16 bits of the 28th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address27 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address27_Low on page 17-405
The MAC Address27 Low register holds the lower 32 bits of the 28th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address28_High on page 17-406
The MAC Address28 High register holds the upper 16 bits of the 29th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address28 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address28_Low on page 17-409
The MAC Address28 Low register holds the lower 32 bits of the 29th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address29_High on page 17-410
The MAC Address29 High register holds the upper 16 bits of the 30th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address29 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address29_Low on page 17-413
The MAC Address29 Low register holds the lower 32 bits of the 30th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address30_High on page 17-414
The MAC Address30 High register holds the upper 16 bits of the 31th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address30 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address30_Low on page 17-417
The MAC Address30 Low register holds the lower 32 bits of the 31th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address31_High on page 17-418
The MAC Address31 High register holds the upper 16 bits of the 32th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address31 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address31_Low on page 17-421
The MAC Address31 Low register holds the lower 32 bits of the 32th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address32_High on page 17-422
The MAC Address32 High register holds the upper 16 bits of the 33th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address32 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address32_Low on page 17-425
The MAC Address32 Low register holds the lower 32 bits of the 33th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address33_High on page 17-426
The MAC Address33 High register holds the upper 16 bits of the 34th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address33 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address33_Low on page 17-429
The MAC Address33 Low register holds the lower 32 bits of the 34th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address34_High on page 17-430
The MAC Address34 High register holds the upper 16 bits of the 35th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address34 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address34_Low on page 17-433
The MAC Address34 Low register holds the lower 32 bits of the 35th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address35_High on page 17-434
The MAC Address35 High register holds the upper 16 bits of the 36th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address35 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address35_Low on page 17-437
The MAC Address35 Low register holds the lower 32 bits of the 36th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address36_High on page 17-438
The MAC Address36 High register holds the upper 16 bits of the 37th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address36 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address36_Low on page 17-441
The MAC Address36 Low register holds the lower 32 bits of the 37th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address37_High on page 17-442
The MAC Address37 High register holds the upper 16 bits of the 38th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address37 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address37_Low on page 17-445
The MAC Address37 Low register holds the lower 32 bits of the 38th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address38_High on page 17-446
The MAC Address38 High register holds the upper 16 bits of the 39th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address38 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address38_Low on page 17-449
The MAC Address38 Low register holds the lower 32 bits of the 39th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address39_High on page 17-450
The MAC Address39 High register holds the upper 16 bits of the 40th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address39 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address39_Low on page 17-453
The MAC Address39 Low register holds the lower 32 bits of the 40th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address40_High on page 17-454
The MAC Address40 High register holds the upper 16 bits of the 41th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address40 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address40_Low on page 17-457
The MAC Address40 Low register holds the lower 32 bits of the 41th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address41_High on page 17-458
The MAC Address41 High register holds the upper 16 bits of the 42th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address41 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address41_Low on page 17-461
The MAC Address41 Low register holds the lower 32 bits of the 42th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address42_High on page 17-462
The MAC Address42 High register holds the upper 16 bits of the 43th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address42 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address42_Low on page 17-465
The MAC Address42 Low register holds the lower 32 bits of the 43th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address43_High on page 17-466
The MAC Address43 High register holds the upper 16 bits of the 44th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address43 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address43_Low on page 17-469
The MAC Address43 Low register holds the lower 32 bits of the 44th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address44_High on page 17-470
The MAC Address44 High register holds the upper 16 bits of the 45th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address44 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address44_Low on page 17-473
The MAC Address44 Low register holds the lower 32 bits of the 45th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address45_High on page 17-474
The MAC Address45 High register holds the upper 16 bits of the 46th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address45 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address45_Low on page 17-477
The MAC Address45 Low register holds the lower 32 bits of the 46th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address46_High on page 17-478
The MAC Address46 High register holds the upper 16 bits of the 47th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address46 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address46_Low on page 17-481
The MAC Address46 Low register holds the lower 32 bits of the 47th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address47_High on page 17-482
The MAC Address47 High register holds the upper 16 bits of the 48th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address47 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address47_Low on page 17-485
The MAC Address47 Low register holds the lower 32 bits of the 48th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address48_High on page 17-486
The MAC Address48 High register holds the upper 16 bits of the 49th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address48 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address48_Low on page 17-489
The MAC Address48 Low register holds the lower 32 bits of the 49th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address49_High on page 17-490
The MAC Address49 High register holds the upper 16 bits of the 50th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address49 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address49_Low on page 17-493
The MAC Address49 Low register holds the lower 32 bits of the 50th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address50_High on page 17-494
The MAC Address50 High register holds the upper 16 bits of the 51th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address50 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address50_Low on page 17-497
The MAC Address50 Low register holds the lower 32 bits of the 51th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address51_High on page 17-498
The MAC Address51 High register holds the upper 16 bits of the 52th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address51 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address51_Low on page 17-501
The MAC Address51 Low register holds the lower 32 bits of the 52th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address52_High on page 17-502
The MAC Address52 High register holds the upper 16 bits of the 53th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address52 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address52_Low on page 17-505
The MAC Address52 Low register holds the lower 32 bits of the 53th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address53_High on page 17-506
The MAC Address53 High register holds the upper 16 bits of the 54th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address53 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address53_Low on page 17-509
The MAC Address53 Low register holds the lower 32 bits of the 54th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address54_High on page 17-510
The MAC Address54 High register holds the upper 16 bits of the 55th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address54 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address54_Low on page 17-513
The MAC Address54 Low register holds the lower 32 bits of the 55th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address55_High on page 17-514
The MAC Address55 High register holds the upper 16 bits of the 56th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address55 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address55_Low on page 17-517
The MAC Address55 Low register holds the lower 32 bits of the 56th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address56_High on page 17-518
The MAC Address56 High register holds the upper 16 bits of the 57th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address56 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address56_Low on page 17-521
The MAC Address56 Low register holds the lower 32 bits of the 57th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address57_High on page 17-522
The MAC Address57 High register holds the upper 16 bits of the 58th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address57 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address57_Low on page 17-525
The MAC Address57 Low register holds the lower 32 bits of the 58th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address58_High on page 17-526
The MAC Address58 High register holds the upper 16 bits of the 59th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address58 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address58_Low on page 17-529
The MAC Address58 Low register holds the lower 32 bits of the 59th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address59_High on page 17-530
The MAC Address59 High register holds the upper 16 bits of the 60th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address59 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address59_Low on page 17-533
The MAC Address59 Low register holds the lower 32 bits of the 60th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address60_High on page 17-534
The MAC Address60 High register holds the upper 16 bits of the 61th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address60 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address60_Low on page 17-537
The MAC Address60 Low register holds the lower 32 bits of the 61th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address61_High on page 17-538
The MAC Address61 High register holds the upper 16 bits of the 62th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address61 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address61_Low on page 17-541
The MAC Address61 Low register holds the lower 32 bits of the 62th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address62_High on page 17-542
The MAC Address62 High register holds the upper 16 bits of the 63th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address62 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address62_Low on page 17-545
The MAC Address62 Low register holds the lower 32 bits of the 63th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address63_High on page 17-546
The MAC Address63 High register holds the upper 16 bits of the 64th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address63 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address63_Low on page 17-549
The MAC Address63 Low register holds the lower 32 bits of the 64th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address64_High on page 17-550
The MAC Address64 High register holds the upper 16 bits of the 65th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address64 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address64_Low on page 17-553
The MAC Address64 Low register holds the lower 32 bits of the 65th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address65_High on page 17-554
The MAC Address65 High register holds the upper 16 bits of the 66th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address65 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address65_Low on page 17-557
The MAC Address65 Low register holds the lower 32 bits of the 66th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address66_High on page 17-558
The MAC Address66 High register holds the upper 16 bits of the 67th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address66 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address66_Low on page 17-561
The MAC Address66 Low register holds the lower 32 bits of the 67th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address67_High on page 17-562
The MAC Address67 High register holds the upper 16 bits of the 68th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address67 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address67_Low on page 17-565
The MAC Address67 Low register holds the lower 32 bits of the 68th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address68_High on page 17-566
The MAC Address68 High register holds the upper 16 bits of the 69th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address68 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address68_Low on page 17-569
The MAC Address68 Low register holds the lower 32 bits of the 69th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address69_High on page 17-570
The MAC Address69 High register holds the upper 16 bits of the 70th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address69 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address69_Low on page 17-573
The MAC Address69 Low register holds the lower 32 bits of the 70th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address70_High on page 17-574
The MAC Address70 High register holds the upper 16 bits of the 71th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address70 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address70_Low on page 17-577
The MAC Address70 Low register holds the lower 32 bits of the 71th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address71_High on page 17-578
The MAC Address71 High register holds the upper 16 bits of the 72th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address71 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address71_Low on page 17-581
The MAC Address71 Low register holds the lower 32 bits of the 72th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address72_High on page 17-582
The MAC Address72 High register holds the upper 16 bits of the 73th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address72 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address72_Low on page 17-585
The MAC Address72 Low register holds the lower 32 bits of the 73th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address73_High on page 17-586
The MAC Address73 High register holds the upper 16 bits of the 74th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address73 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address73_Low on page 17-589
The MAC Address73 Low register holds the lower 32 bits of the 74th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address74_High on page 17-590
The MAC Address74 High register holds the upper 16 bits of the 75th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address74 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address74_Low on page 17-593
The MAC Address74 Low register holds the lower 32 bits of the 75th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address75_High on page 17-594
The MAC Address75 High register holds the upper 16 bits of the 76th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address75 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address75_Low on page 17-597
The MAC Address75 Low register holds the lower 32 bits of the 76th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address76_High on page 17-598
The MAC Address76 High register holds the upper 16 bits of the 77th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address76 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address76_Low on page 17-601
The MAC Address76 Low register holds the lower 32 bits of the 77th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address77_High on page 17-602
The MAC Address77 High register holds the upper 16 bits of the 78th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address77 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address77_Low on page 17-605
The MAC Address77 Low register holds the lower 32 bits of the 78th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address78_High on page 17-606
The MAC Address78 High register holds the upper 16 bits of the 79th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address78 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address78_Low on page 17-609
The MAC Address78 Low register holds the lower 32 bits of the 79th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address79_High on page 17-610
The MAC Address79 High register holds the upper 16 bits of the 80th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address79 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address79_Low on page 17-613
The MAC Address79 Low register holds the lower 32 bits of the 80th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address80_High on page 17-614
The MAC Address80 High register holds the upper 16 bits of the 81th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address80 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address80_Low on page 17-617
The MAC Address80 Low register holds the lower 32 bits of the 81th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address81_High on page 17-618
The MAC Address81 High register holds the upper 16 bits of the 82th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address81 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address81_Low on page 17-621
The MAC Address81 Low register holds the lower 32 bits of the 82th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address82_High on page 17-622
The MAC Address82 High register holds the upper 16 bits of the 83th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address82 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address82_Low on page 17-625
The MAC Address82 Low register holds the lower 32 bits of the 83th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address83_High on page 17-626
The MAC Address83 High register holds the upper 16 bits of the 84th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address83 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address83_Low on page 17-629
The MAC Address83 Low register holds the lower 32 bits of the 84th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address84_High on page 17-630
The MAC Address84 High register holds the upper 16 bits of the 85th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address84 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address84_Low on page 17-633
The MAC Address84 Low register holds the lower 32 bits of the 85th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address85_High on page 17-634
The MAC Address85 High register holds the upper 16 bits of the 86th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address85 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address85_Low on page 17-637
The MAC Address85 Low register holds the lower 32 bits of the 86th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address86_High on page 17-638
The MAC Address86 High register holds the upper 16 bits of the 87th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address86 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address86_Low on page 17-641
The MAC Address86 Low register holds the lower 32 bits of the 87th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address87_High on page 17-642
The MAC Address87 High register holds the upper 16 bits of the 88th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address87 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address87_Low on page 17-645
The MAC Address87 Low register holds the lower 32 bits of the 88th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address88_High on page 17-646
The MAC Address88 High register holds the upper 16 bits of the 89th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address88 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address88_Low on page 17-649
The MAC Address88 Low register holds the lower 32 bits of the 89th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address89_High on page 17-650
The MAC Address89 High register holds the upper 16 bits of the 90th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address89 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address89_Low on page 17-653
The MAC Address89 Low register holds the lower 32 bits of the 90th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address90_High on page 17-654
The MAC Address90 High register holds the upper 16 bits of the 91th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address90 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address90_Low on page 17-657
The MAC Address90 Low register holds the lower 32 bits of the 91th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address91_High on page 17-658
The MAC Address91 High register holds the upper 16 bits of the 92th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address91 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address91_Low on page 17-661
The MAC Address91 Low register holds the lower 32 bits of the 92th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address92_High on page 17-662
The MAC Address92 High register holds the upper 16 bits of the 93th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address92 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address92_Low on page 17-665
The MAC Address92 Low register holds the lower 32 bits of the 93th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address93_High on page 17-666
The MAC Address93 High register holds the upper 16 bits of the 94th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address93 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address93_Low on page 17-669
The MAC Address93 Low register holds the lower 32 bits of the 94th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address94_High on page 17-670
The MAC Address94 High register holds the upper 16 bits of the 95th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address94 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address94_Low on page 17-673
The MAC Address94 Low register holds the lower 32 bits of the 95th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address95_High on page 17-674
The MAC Address95 High register holds the upper 16 bits of the 96th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address95 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address95_Low on page 17-677
The MAC Address95 Low register holds the lower 32 bits of the 96th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address96_High on page 17-678
The MAC Address96 High register holds the upper 16 bits of the 97th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address96 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address96_Low on page 17-681
The MAC Address96 Low register holds the lower 32 bits of the 97th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address97_High on page 17-682
The MAC Address97 High register holds the upper 16 bits of the 98th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address97 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address97_Low on page 17-685
The MAC Address97 Low register holds the lower 32 bits of the 98th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address98_High on page 17-686
The MAC Address98 High register holds the upper 16 bits of the 99th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address98 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address98_Low on page 17-689
The MAC Address98 Low register holds the lower 32 bits of the 99th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address99_High on page 17-690
The MAC Address99 High register holds the upper 16 bits of the 100th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address99 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address99_Low on page 17-693
The MAC Address99 Low register holds the lower 32 bits of the 100th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address100_High on page 17-694
The MAC Address100 High register holds the upper 16 bits of the 101th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address100 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address100_Low on page 17-697
The MAC Address100 Low register holds the lower 32 bits of the 101th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address101_High on page 17-698
The MAC Address101 High register holds the upper 16 bits of the 102th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address101 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address101_Low on page 17-701
The MAC Address101 Low register holds the lower 32 bits of the 102th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address102_High on page 17-702
The MAC Address102 High register holds the upper 16 bits of the 103th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address102 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address102_Low on page 17-705
The MAC Address102 Low register holds the lower 32 bits of the 103th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address103_High on page 17-706
The MAC Address103 High register holds the upper 16 bits of the 104th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address103 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address103_Low on page 17-709
The MAC Address103 Low register holds the lower 32 bits of the 104th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address104_High on page 17-710
The MAC Address104 High register holds the upper 16 bits of the 105th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address104 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address104_Low on page 17-713
The MAC Address104 Low register holds the lower 32 bits of the 105th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address105_High on page 17-714
The MAC Address105 High register holds the upper 16 bits of the 106th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address105 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address105_Low on page 17-717
The MAC Address105 Low register holds the lower 32 bits of the 106th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address106_High on page 17-718
The MAC Address106 High register holds the upper 16 bits of the 107th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address106 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address106_Low on page 17-721
The MAC Address106 Low register holds the lower 32 bits of the 107th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address107_High on page 17-722
The MAC Address107 High register holds the upper 16 bits of the 108th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address107 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address107_Low on page 17-725
The MAC Address107 Low register holds the lower 32 bits of the 108th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address108_High on page 17-726
The MAC Address108 High register holds the upper 16 bits of the 109th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address108 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address108_Low on page 17-729
The MAC Address108 Low register holds the lower 32 bits of the 109th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address109_High on page 17-730
The MAC Address109 High register holds the upper 16 bits of the 110th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address109 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address109_Low on page 17-733
The MAC Address109 Low register holds the lower 32 bits of the 110th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address110_High on page 17-734
The MAC Address110 High register holds the upper 16 bits of the 111th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address110 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address110_Low on page 17-737
The MAC Address110 Low register holds the lower 32 bits of the 111th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address111_High on page 17-738
The MAC Address111 High register holds the upper 16 bits of the 112th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address111 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address111_Low on page 17-741
The MAC Address111 Low register holds the lower 32 bits of the 112th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address112_High on page 17-742
The MAC Address112 High register holds the upper 16 bits of the 113th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address112 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address112_Low on page 17-745
The MAC Address112 Low register holds the lower 32 bits of the 113th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address113_High on page 17-746
The MAC Address113 High register holds the upper 16 bits of the 114th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address113 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address113_Low on page 17-749
The MAC Address113 Low register holds the lower 32 bits of the 114th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address114_High on page 17-750
The MAC Address114 High register holds the upper 16 bits of the 115th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address114 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address114_Low on page 17-753
The MAC Address114 Low register holds the lower 32 bits of the 115th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address115_High on page 17-754
The MAC Address115 High register holds the upper 16 bits of the 116th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address115 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address115_Low on page 17-757
The MAC Address115 Low register holds the lower 32 bits of the 116th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address116_High on page 17-758
The MAC Address116 High register holds the upper 16 bits of the 117th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address116 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address116_Low on page 17-761
The MAC Address116 Low register holds the lower 32 bits of the 117th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address117_High on page 17-762
The MAC Address117 High register holds the upper 16 bits of the 118th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address117 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address117_Low on page 17-765
The MAC Address117 Low register holds the lower 32 bits of the 118th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address118_High on page 17-766
The MAC Address118 High register holds the upper 16 bits of the 119th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address118 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address118_Low on page 17-769
The MAC Address118 Low register holds the lower 32 bits of the 119th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address119_High on page 17-770
The MAC Address119 High register holds the upper 16 bits of the 120th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address119 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address119_Low on page 17-773
The MAC Address119 Low register holds the lower 32 bits of the 120th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address120_High on page 17-774
The MAC Address120 High register holds the upper 16 bits of the 121th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address120 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address120_Low on page 17-777
The MAC Address120 Low register holds the lower 32 bits of the 121th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address121_High on page 17-778
The MAC Address121 High register holds the upper 16 bits of the 122th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address121 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address121_Low on page 17-781
The MAC Address121 Low register holds the lower 32 bits of the 122th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address122_High on page 17-782
The MAC Address122 High register holds the upper 16 bits of the 123th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address122 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address122_Low on page 17-785
The MAC Address122 Low register holds the lower 32 bits of the 123th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address123_High on page 17-786
The MAC Address123 High register holds the upper 16 bits of the 124th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address123 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address123_Low on page 17-789
The MAC Address123 Low register holds the lower 32 bits of the 124th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address124_High on page 17-790
The MAC Address124 High register holds the upper 16 bits of the 125th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address124 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address124_Low on page 17-793
The MAC Address124 Low register holds the lower 32 bits of the 125th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address125_High on page 17-794
The MAC Address125 High register holds the upper 16 bits of the 126th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address125 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address125_Low on page 17-797
The MAC Address125 Low register holds the lower 32 bits of the 126th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address126_High on page 17-798
The MAC Address126 High register holds the upper 16 bits of the 127th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address126 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address126_Low on page 17-801
The MAC Address126 Low register holds the lower 32 bits of the 127th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Address127_High on page 17-802
The MAC Address127 High register holds the upper 16 bits of the 128th 6-byte MAC address of the station. Because the MAC address registers are configured to be double-synchronized to the (G)MII clock domains, the synchronization is triggered only when bits[31:24] (in little-endian mode) or Bits[7:0] (in big-endian mode) of the MAC Address127 Low Register are written. For proper synchronization updates, the consecutive writes to this Address Low Register should be performed after at least four clock cycles in the destination clock domain. Note that all MAC Address High registers (except MAC Address0 High) have the same format.

MAC_Address127_Low on page 17-805
The MAC Address127 Low register holds the lower 32 bits of the 128th 6-byte MAC address of the station. Note that all MAC Address Low registers (except MAC Address0 Low) have the same format.

MAC_Configuration

The MAC Configuration register establishes receive and transmit operating modes.

Module Instance	Base Address	Register Address
emac0	0xFF700000	0xFF700000

MAC_Configuration Fields

Bit	Name	Description	Access	Reset
27	twokpe	When set, the MAC considers all frames, with up to 2,000 bytes length, as normal packets. When Bit 20 (Jumbo Enable) is not set, the MAC considers all received frames of size more than 2K bytes as Giant frames. When this bit is reset and Bit 20 (Jumbo Enable) is not set, the MAC considers all received frames of size more than 1,518 bytes (1,522 bytes for tagged) as Giant frames. When Bit 20 (Jumbo Enable) is set, setting this bit has no effect on Giant Frame status.	RW	0x0
25	cst	When set, the last 4 bytes (FCS) of all frames of Ether type (type field greater than 0x0600) are stripped and dropped before forwarding the frame to the application. This function is not valid when the IP Checksum Engine (Type 1) is enabled in the MAC receiver. **Value** **Description** 0x0 Strip Ether Frames Off 0x1 Strip Ether Frames On	RW	0x0
24	tc	When set, this bit enables the transmission of duplex mode, link speed, and link up or down information to the PHY in the RGMII. When this bit is reset, no such information is driven to the PHY. **Value** **Description** 0x1 Enables Transmission of duplex 0x0 Disables Transmission to Phy	RW	0x0

Bit	Name	Description	Access	Reset
14	fes	This bit selects the speed in the RMII/RGMII interface: * 0: 10 Mbps * 1: 100 Mbps This bit generates link speed encoding when TC (Bit 24) is set in the RGMII, SMII, or SGMII mode. **Value** **Description** 0x0 Speed = 10 Mbps 0x1 Speed = 100 Mbps	RW	0x0
13	do	When this bit is set, the MAC disables the reception of frames when the gmii_txen_o is asserted in the half-duplex mode. When this bit is reset, the MAC receives all packets that are given by the PHY while transmitting. This bit is not applicable if the MAC is operating in the full-duplex mode. **Value** **Description** 0x0 MAC Enables Reception of Frames 0x1 MAC Disables Reception of Frames	RW	0x0
12	lm	When this bit is set, the MAC operates in the loopback mode at GMII or MII. The (G)MII Receive clock input is required for the loopback to work properly, because the Transmit clock is not looped-back internally. **Value** **Description** 0x0 Disable Loop Back 0x1 Enable Loop Back	RW	0x0
11	dm	When this bit is set, the MAC operates in the full-duplex mode where it can transmit and receive simultaneously. **Value** **Description** 0x1 MAC Full Duplex Enabled 0x0 MAC Full Duplex Disabled	RW	0x0

Bit	Name	Description	Access	Reset
10	`ipc`	When this bit is set, the MAC calculates the 16-bit ones complement of the ones complement sum of all received Ethernet frame payloads. It also checks whether the IPv4 Header checksum (assumed to be bytes 2526 or 2930 (VLAN-tagged) of the received Ethernet frame) is correct for the received frame and gives the status in the receive status word. The MAC also appends the 16-bit checksum calculated for the IP header datagram payload (bytes after the IPv4 header) and appends it to the Ethernet frame transferred to the application (when Type 2 COE is deselected). When this bit is reset, this function is disabled. When Type 2 COE is selected, this bit, when set, enables the IPv4 header checksum checking and IPv4 or IPv6 TCP, UDP, or ICMP payload checksum checking. When this bit is reset, the COE function in the receiver is disabled and the corresponding PCE and IP HCE status bits are always cleared. **Value** — **Description** 0x1 — Checksum Enabled 0x0 — Checksum Disabled	`RW`	`0x0`
9	`dr`	When this bit is set, the MAC attempts only one transmission. When a collision occurs on the GMII or MII interface, the MAC ignores the current frame transmission and reports a Frame Abort with excessive collision error in the transmit frame status. When this bit is reset, the MAC attempts retries based on the settings of the BL field (Bits [6:5]). This bit is applicable only in the half-duplex mode. **Value** — **Description** 0x1 — MAC attempts one transmission 0x0 — MAC attempts retries per bl Field	`RW`	`0x0`
8	`lud`	This bit indicates whether the link is up or down during the transmission of configuration in the RGMII, SGMII, or SMII interface **Value** — **Description** 0x0 — Link Down 0x1 — Link Up	`RW`	`0x0`

Bit	Name	Description	Access	Reset
7	acs	When this bit is set, the MAC strips the Pad or FCS field on the incoming frames only if the value of the length field is less than 1,536 bytes. All received frames with length field greater than or equal to 1,536 bytes are passed to the application without stripping the Pad or FCS field. When this bit is reset, the MAC passes all incoming frames, without modifying them, to the Host. **Value** **Description** 0x0 Disable Automatic Pad CRC Stripping 0x1 Enable Automatic Pad CRC Stripping	RW	0x0
6:5	bl	The Back-Off limit determines the random integer number (r) of slot time delays (4,096 bit times for 1000 Mbps and 512 bit times for 10/100 Mbps) for which the MAC waits before rescheduling a transmission attempt during retries after a collision. This bit is applicable only in the half-duplex mode. * 00: k = min (n, 10) * 01: k = min (n, 8) * 10: k = min (n, 4) * 11: k = min (n, 1) where <i> n </i>= retransmission attempt. The random integer <i> r </i> takes the value in the range 0 <= r < kth power of 2 **Value** **Description** 0x0 k = min (n, 10) 0x1 k = min (n, 8) 0x2 k = min (n, 4) 0x3 k = min (n, 1)	RW	0x0

Bit	Name	Description	Access	Reset
4	dc	When this bit is set, the deferral check function is enabled in the MAC. The MAC issues a Frame Abort status, along with the excessive deferral error bit set in the transmit frame status, when the transmit state machine is deferred for more than 24,288 bit times in the 10 or 100 Mbps mode. If the MAC is configured for 1000 Mbps operation, or if the Jumbo frame mode is enabled in the 10 or 100 Mbps mode, the threshold for deferral is 155,680 bits times. Deferral begins when the transmitter is ready to transmit, but is prevented because of an active carrier sense signal (CRS) on GMII or MII. Defer time is not cumulative. When the transmitter defers for 10,000 bit times, it transmits, collides, backs off, and then defers again after completion of back-off. The deferral timer resets to 0 and restarts. When this bit is reset, the deferral check function is disabled and the MAC defers until the CRS signal goes inactive. This bit is applicable only in the half-duplex mode. **Value** **Description** 0x1 Deferral Check Enabled 0x0 Deferral Check Disabled	RW	0x0
3	te	When this bit is set, the transmit state machine of the MAC is enabled for transmission on the GMII or MII. When this bit is reset, the MAC transmit state machine is disabled after the completion of the transmission of the current frame, and does not transmit any further frames. **Value** **Description** 0x0 MAC transmit state machine disabled 0x1 MAC transmit state machine disabled	RW	0x0
2	re	When this bit is set, the receiver state machine of the MAC is enabled for receiving frames from the GMII or MII. When this bit is reset, the MAC receive state machine is disabled after the completion of the reception of the current frame, and does not receive any further frames from the GMII or MII. **Value** **Description** 0x0 MAC receive state machine disabled 0x1 MAC receive state machine enabled	RW	0x0

Bit	Name	Description	Access	Reset
1:0	`prelen`	These bits control the number of preamble bytes that are added to the beginning of every Transmit frame. The preamble reduction occurs only when the MAC is operating **Value** — **Description** 0x0 — Preamble 7 Bytes 0x1 — Preamble 5 Bytes 0x2 — Preamble 3 Bytes	RW	0x0

MAC_Frame_Filter

The MAC Frame Filter register contains the filter controls for receiving frames. Some of the controls from this register go to the address check block of the MAC, which performs the first level of address filtering. The second level of filtering is performed on the incoming frame, based on other controls such as Pass Bad Frames and Pass Control Frames.

Module Instance	Base Address	Register Address
emac0	0xFF700000	0xFF700004
emac1	0xFF702000	0xFF702004

MAC_Frame_Filter Fields

Bit	Name	Description	Access	Reset
31	`ra`	When this bit is set, the MAC Receiver block passes all received frames, irrespective of whether they pass the address filter or not, to the Application. The result of the SA or DA filtering is updated (pass or fail) in the corresponding bits in the Receive Status Word. When this bit is reset, the Receiver block passes only those frames to the Application that pass the SA or DA address filter. **Value** — **Description** 0x0 — Receive All off 0x1 — Receive All On	RW	0x0
21	`dntu`	When set, this bit enables the MAC to drop the non-TCP or UDP over IP frames. The MAC forward only those frames that are processed by the Layer 4 filter. When reset, this bit enables the MAC to forward all non-TCP or UDP over IP frames. **Value** — **Description** 0x0 — Forward all non-TCP or UDP over IP frames 0x1 — Drop non-TCP or UDP over IP frames	RW	0x0
20	`ipfe`	When set, this bit enables the MAC to drop frames that do not match the enabled Layer 3 and Layer 4 filters. If Layer 3 or Layer 4 filters are not enabled for matching, this bit does not have any effect. When reset, the MAC forwards all frames irrespective of the match status of the Layer 3 and Layer 4 filters. **Value** — **Description** 0x0 — Forward all frames irrespective of the match status of Layer 3 and Layer 4 filters 0x1 — Drop frames that do not match the enabled Layer 3 and Layer 4 filters	RW	0x0

Bit	Name	Description	Access	Reset
16	`vtfe`	When set, this bit enables the MAC to drop VLAN tagged frames that do not match the VLAN Tag comparison. When reset, the MAC forwards all frames irrespective of the match status of the VLAN Tag. **Value** **Description** 0x0 Forward all frames irrespective of the match status of the VLAN tag 0x1 Drop VLAN tagged frames that do not match the VLAN Tag comparison	RW	0x0
10	`hpf`	When this bit is set, it configures the address filter to pass a frame if it matches either the perfect filtering or the hash filtering as set by the HMC or HUC bits. When this bit is low and the HUC or HMC bit is set, the frame is passed only if it matches the Hash filter. **Value** **Description** 0x0 Hash or Perfect Filter off 0x1 Hash or Perfect Filter on	RW	0x0
9	`saf`	When this bit is set, the MAC compares the SA field of the received frames with the values programmed in the enabled SA registers. If the comparison matches, then the SA Match bit of RxStatus Word is set high. When this bit is set high and the SA filter fails, the MAC drops the frame. When this bit is reset, the MAC forwards the received frame to the application and with the updated SA Match bit of the RxStatus depending on the SA address comparison. **Value** **Description** 0x0 SA Filter Off 0x1 SA Filter On	RW	0x0

<table>
<tr><th>Bit</th><th>Name</th><th>Description</th><th>Access</th><th>Reset</th></tr>
<tr><td>8</td><td>saif</td><td>When this bit is set, the Address Check block operates in inverse filtering mode for the SA address comparison. The frames whose SA matches the SA registers are marked as failing the SA Address filter. When this bit is reset, frames whose SA does not match the SA registers are marked as failing the SA Address filter.
<table>

<tr><td>7:6</td><td>pcf</td><td>These bits control the forwarding of all control frames (including unicast and multicast PAUSE frames). * 00: MAC filters all control frames from reaching the application. * 01: MAC forwards all control frames except PAUSE control frames to application even if they fail the Address filter. * 10: MAC forwards all control frames to application even if they fail the Address Filter. * 11: MAC forwards control frames that pass the Address Filter. The following conditions should be true for the PAUSE control frames processing: * Condition 1: The MAC is in the full-duplex mode and flow control is enabled by setting Bit 2 (RFE) of Register 6 (Flow Control Register) to 1. * Condition 2: The destination address (DA) of the received frame matches the special multicast address or the MAC Address 0 when Bit 3 (UP) of the Register 6 (Flow Control Register) is set. * Condition 3: The Type field of the received frame is 0x8808 and the OPCODE field is 0x0001. This field should be set to 01 only when the Condition 1 is true, that is, the MAC is programmed to operate in the full-duplex mode and the RFE bit is enabled. Otherwise, the PAUSE frame filtering may be inconsistent. When Condition 1 is false, the PAUSE frames are considered as generic control frames. Therefore, to pass all control frames (including PAUSE control frames) when the full-duplex mode and flow control is not enabled, you should set the PCF field to 10 or 11 (as required by the application).
<table>
<tr><th>Value</th><th>Description</th></tr>

GMII_Address Fields

Bit	Name	Description	Access	Reset
15:11	pa	This field indicates which of the 32 possible PHY devices are being accessed. For RevMII, this field gives the PHY Address of the RevMII block.	RW	0x0
10:6	gr	These bits select the desired GMII register in the selected PHY device. For RevMII, these bits select the desired CSR register in the RevMII Registers set.	RW	0x0

Bit	Name	Description	Access	Reset
5:2	cr	The CSR Clock Range selection determines the frequency of the MDC clock according to the l3_sp_clk frequency used in your design. The suggested range of l3_sp_clk frequency applicable for each value (when Bit[5] = 0) ensures that the MDC clock is approximately between the frequency range 1.0 MHz - 2.5 MHz. When Bit 5 is set, you can achieve MDC clock of frequency higher than the IEEE 802.3 specified frequency limit of 2.5 MHz and program a clock divider of lower value. For example, when l3_sp_clk is of 100 MHz frequency and you program these bits as 1010, then the resultant MDC clock is of 12.5 MHz which is outside the limit of IEEE 802.3 specified range. Only use the values larger than 7 if the interfacing chips support faster MDC clocks. **Value** **Description** 0x0 l3_sp_clk 60-100Mhz and MDC clock = l3_sp_clk/42 0x1 l3_sp_clk 100-150Mhz and MDC clock = l3_sp_clk/62 0x2 l3_sp_clk 25-35Mhz and MDC clock = l3_sp_clk/16 0x3 l3_sp_clk 35-60Mhz and MDC clock = l3_sp_clk/26 0x4 l3_sp_clk 150-250Mhz and MDC clock = l3_sp_clk/102 0x5 l3_sp_clk 250-300Mhz and MDC clock = l3_sp_clk/124 0x8 l3_sp_clk/4 0x9 l3_sp_clk/6 0xa l3_sp_clk/8 0xb l3_sp_clk/10 0xc l3_sp_clk/12 0xd l3_sp_clk/14 0xe l3_sp_clk/16 0xf l3_sp_clk/18	RW	0x0
